

The University of Toronto
Chemical Library

Presented
to

The University of Toronto Library
by

William Lash Miller, B.A., Ph.D., C.B.E.

Professor Emeritus of Physical Chemistry
for

A Departmental Library to be under
the control of the Professor of

Chemistry, according to the conditions
set out in a letter from the Librarian
of the University dated March 21st

1938.

THE SOCIETY OF CHEMICAL INDUSTRY

LIST OF PAPERS PRESENTED TO THE SOCIETY AND PUBLISHED IN THE JOURNAL DURING 1918

N.B.—The words within () indicate the Section of the Society (if any) before which the paper was read and the issue of the Journal in which it appears.

	PAGE		PAGE
Anfilogoff, N. A. Distillation test of petrol. (Jan. 15)	21T	Bywaters, H. W. <i>See</i> Batten, L.	242T
Annett, H. E., and H. Singh. The effect of heating opium on its morphine content. (Nottingham, Dec. 16)	315T	Caven, R. M. Soluble glass. (Nottingham, Feb. 28)	63T
Babington, F. W., and others. The examination of commercial dextrin and related starch products. (Canadian, Aug. 15)	257T	Challinor, R. W. Some advantages to be derived by the utilisation of waste on the south coast of New South Wales. (Sydney, Dec. 31)	337T
Balley, T. L. The manufacture of tinplate. (Liverpool, Apr. 15)	113T	Chance, K. M. The prospects of founding a potash industry in this country. (Annual Meeting, July 31)	222T
Barger, G. Poisons and drugs of animal origin. (Nottingham, Jan. 31)	32T	Clare, G. R. Notes on exhaust gas analysis. (Feb. 15)	51T
Barker, B. T. P. Cider apple jelly. (Annual Meeting, July 31)	243T	Clifford, W. Utilisation of waste Nessler solution. (Birmingham, June 29)	179T
Barker, M. F. <i>See</i> Fox, J. J.	265T, 268T	Cocks, L. V., and A. H. Salway. On the quality of glycerin from whale oil. An investigation of the factors influencing the quality of crude glycerin when manufactured by the Twitchell process. (Apr. 30)	126T
Barrowcliff, M. The preparation of "standard" plantation rubber: a new method of coagulation. (Nottingham, Mar. 30)	95T	Collitt, B., and W. Regan. The analysis of aluminium alloys. (Nottingham, Mar. 30, May 15)	91T, 142T
Theory of the coagulation of Hevea latex. (Nottingham, Feb. 15, Aug. 15)	48T, 262T	Colman, H. G., and E. W. Yeoman. Commercial "concentrated ammoniac-liquor" and its impurities. (London, Dec. 31)	319T
Batten, L., and H. W. Bywaters. Occurrence of mould in cocoa butter. (Annual Meeting, July 31)	242T	Coombs, F. A., and W. H. McGlynn. Tanning in acid liquors, with comparative tests. (Sydney, Mar. 15)	76T
Berry, R. A., and D. N. McArthur. Recovery of potash from blast-furnace dust. (Glasgow, Jan. 15)	1T	Coste, J. H. Absorption of atmospheric gases by water. (London, June 15)	170T
Birchard, F. T. The determination of moisture in wheat. (Canadian, Aug. 31)	263T	Craggs, J. W. Notes on testing hardness of metals. (Newcastle, Feb. 15)	43T
Boyer, E. D. The manufacture of Portland cement. (Jan. 15)	19T	Denbigh, G. J. The influence of temperature on the decomposition of sodium carbonate and cresylates by carbon dioxide. (Nov. 15)	306T
Brame, J. S. S. The action of rain water on a Portland stone. (London, Feb. 15)	40T	Desch, C. H. The preservation of building stone. (Glasgow, Apr. 30)	118T
Corrosion of lead roofing. (London, Feb. 15, Mar. 30)	39T, 85T	De Segundo, E. C. Some cottonseed products in their relation to present-day needs. (London, Apr. 30)	118T
Branson, F. W. Some aspects of the scientific glassware industry. (Yorkshire, Dec. 31)	337T	<i>Errata</i> (June 15)	172T
Burrell, B. A. <i>See</i> Fairley, T.	155T, 155T	Diamond, W. Estimation of sulphur in spent oxide. (Newcastle, Dec. 31)	236T
Butler, T. H. Modern practices in coal tar distillation. (Bristol and South Wales, Jan. 31)	23T		
and F. J. W. Popham. Notes on the commercial fractional separation of benzene, toluene, and xylenes. (Annual Meeting, July 31)	220T		

	PAGE		PAGE
Dunn, J. T. The melting point of coal ash. (Newcastle, Jan. 15)	15T	Kewley, J. Note on a curious case of condenser tube corrosion. (Bristol and South Wales, Feb. 15)	39T
Earl, J. C. Notes on cineol. (Sydney, Aug. 31)	274T	Knapp, A. W. The separation and uses of cacao shell. (Annual Meeting, July 31)	240T
Edwards, A. Approximate estimation of tar fog in gas. (Yorkshire, Jan. 31)	35T	Kober, P. A. Technical applications of nephelometry. (New York, Mar. 15)	75T
Note upon apparatus for the determination of boiling points. (Yorkshire, Jan. 31)	38T	Lal, P. See Nag, N. C.	290T
Ennos, F. R. See Fox, J. J.	328T	Laurie, A. P., and C. Ranken. The preservation of decaying stone. (Edinburgh, May 15)	137T
Evans, E. C. Aspects of the low temperature carbonisation of coal. (Annual Meeting, July 31)	212T	Lawrence, J. C. The distillation of wood. (Glasgow, Jan. 15)	5T
Fairley, T., and B. A. Burrell. Filtering medium used in the estimation of woody fibre. (Yorkshire, May 31)	155T	Leon, M. See Peachey, S. J.	55T
Preliminary note on the presence of bismuth in the human brain. (Yorkshire, May 31)	155T	Lidstone, F. M. A modified mercurial viscometer for determining the viscosity of volatile liquids. (Nottingham, May 31)	148T
Fox, J. J., and M. F. Barker. The estimation of phenol in cresylic acid. (London, Aug. 31)	265T	Louis, H. Presidential address. (Annual Meeting, July 31)	207T
The solidifying and boiling points of phenol and the cresols. (London, Aug. 31)	268T	McArthur, D. N. See Berry, R. A.	1T
and others. The analysis of aluminium alloys and metallic aluminium. (London, Dec. 31)	328T	McBain, J. W. Colloidal electrolytes: soap solutions as a type. (Annual Meeting, July 31)	249T
Francis, F. A method for the determination of the alkalinity of certain solutions. (Annual Meeting, July 31)	252T	McGlynn, W. H. See Coombs, F. A.	76T
Fryer, P. J. Application of the Polenske method to the analysis of soaps and fatty acids. (Aug. 15)	262T	Mansbridge, W. Notes on oil pitch. (Liverpool, June 29)	182T
Grossman, J. The manufacture of nitric acid from nitre cake. (Mar. 30)	103T	Marsden, A. Sources of loss during the manufacture of concentrated ammonia liquor. (Annual Meeting, July 31)	230T
Haanel, B. F. The utilisation of the peat resources of Canada. (Canadian, Aug. 15)	258T	Mathewson, E. P. History of the nickel industry since 1910. (Canadian, Feb. 28)	53T
Hanley, J. A. Lime, and the liming of soils. (Yorkshire, June 29)	185T	Maxted, E. B. Notes on the catalytic and thermal syntheses of ammonia. (Annual Meeting, July 31)	232T
Harvey, T. F., and C. F. Sparks. The rapid estimation of pyridine bases in ammonia and its salts. (London, Feb. 15)	41T	Studies in nitride formation. (Birmingham, Apr. 15)	105T
Heaven, G. S. Fulminate of mercury and its determination. (Birmingham, May 31, June 29)	143T, 190T	Mees, C. E. K. Planning a research laboratory for an industry. (New York, July 15)	201T
Hewson, G. W. Coke as a fuel for the blast-furnace. (Newcastle, Feb. 28)	60T	Miller, E. V., and F. P. Worley. On the relation between the degree of supersaturation, the refractive index, and the temperature of sugar solutions. (Sydney, Mar. 30)	98T
Hill, C. A. See Richmond, H. D.	246T	Millington, E. The influence of small quantities of some metallic elements on the mechanical properties of brass. (Nottingham, May 31)	149T
Hodgkinson, W. R. Deoxidation of copper and copper alloys. (May 31)	158T	Morrell, R. S. The transformation of methyl α -elaeostearate into methyl β -elaeostearate. (Birmingham, June 29)	181T
Some reactions of acetylene. (London, Mar. 30)	86T	Morson, T. D. The toxicity of methyl alcohol in relation to its industrial uses: a review of the published data. (London, Jan. 31)	26T
Hovey, R. W. See Johnsen, B.	132T	Moss, G. L. Modern methods of sulphuric acid manufacture. (Yorkshire, Feb. 28)	68T
Howie, M. Determination of nitrogen content of rubber. (Edinburgh, Mar. 30)	85T	Murray, J. A. Valuation of fertilisers. (Dec. 16)	317T
Inglis, J. H. K. The manufacture of chloramine-T. (Sept. 30)	288T	Nag, N. C., and P. Lal. A simple and rapid method for the estimation of alcohol in spirituous liquors. (Sept. 30)	290T
Johnsen, B. The waste sulphite liquor problem. (Canadian, May 15)	129T	Peachey, S. J., and M. Leon. The oxidation of rubber. (Manchester, Feb. 28)	55T
and R. W. Hovey. The determination of cellulose in wood. (Canadian, May 15)	132T	Pecover, P. See Smart, B. J.	300T
Jones, F. B. Analysis of commercial "pure" benzols. (London, Dec. 31)	324T	Popham, F. J. W. See Butler, T. H.	220T
Kestner, P. The Alsace potash deposits and their economic significance in relation to terms of peace. (London, Nov. 15)	291T		

	PAGE		PAGE
Porritt, B. D. A convenient arrangement for illuminating a chemical balance. (Edinburgh, Mar. 30, May 15) ...	85T, 142T	Sligh, H. See Annett, H. E. ...	315T
Powell, A. R. The determination of tin in high-grade wolfram ores and the use of lead as a reducing agent in Pearce's assay. (London, Sept. 30) ...	285T	Skelton, E. W. See Fox, J. J. ...	328T
Price, T. W. Separation of secondary arylamines from primary amines. (Mar. 15) ...	82T	Snalley, O. The constitution and influence of a cored dendritic structure in alloys. (Newcastle, July 15) ...	191T
Ramsden, W. Vitamines. (Liverpool, Feb. 28) ...	53T	Errata (Aug. 15) ...	261T
Ranken, C. See Laurie, A. P. ...	137T	Smart, B. J., and P. Pecover. Nitration of Posidonoula fibre. (Sydney, Nov. 15) ...	300T
Reavell, J. A. Evaporation in the chemical industry with particular reference to the Kestner evaporator. (Manchester, June 15) ...	172T	Smith, H. G. The use of the refractometer in the examination of eucalyptus oils. (Sydney, Aug. 31) ...	272T
Regan, W. See Collett, B. ...	91T, 142T	Smith, J. L. See Rettle, T. ...	311T
Rettle, T. Antiseptics; a short account of work done for the Medical Research Committee in the Pathological Department, Edinburgh University. (Edinburgh, Jan. 31) ...	23T	Sparks, C. F. See Harvey, T. F. ...	41T
and others. A special bleaching powder for use in hot countries. (Edinburgh and East of Scotland, Dec. 16) ...	311T	Stevens, H. P. Ageing of vulcanised plantation rubber. (Nov. 15, Dec. 31) ...	305T, 340T
Rhead, T. F. E. Residual and extinctive atmospheres of flames. (Aug. 31) ...	274T	The comparative effect of organic and inorganic accelerators in vulcanising rubber. (May 31) ...	156T
Richmond, H. D., and C. A. Hill. Analysis of commercial saccharin. The estimation of <i>o</i> -benzoylsulphonimide from the ammonia produced by acid hydrolysis. (Annual Meeting, July 31) ...	246T	Comparative methods for determining the state of cure of rubber. (Aug. 31) ...	280T
Ritchie, J. See Rettle, T. ...	311T	Thomas, J. S. G. Hot wire anemometry: its principles and applications. (London, June 15) ...	165T
Rixon, F. W. The application of the centrifuge in common laboratory practice. (Annual Meeting, July 31) ...	255T	Tingle, A. The acidimetry of coloured solutions: an application of the pocket spectroscope. (Canadian, Apr. 30) ...	117T
Salway, A. H. On the quality of glycerin from whale oil. An examination of the impurities in glycerin from whale oil with reference to the suitability of such glycerin for the production of dynamite. (Apr. 30) ...	123T	See Babington, F. W. ...	257T
See Cocks, L. V. ...	126T	Travers, M. W. Scientific glassware. (Annual Meeting, July 31) ...	235T
Scragg, H. The deleterious effect of using saline oil coke in the manufacture of carbon electrodes. (Newcastle, Apr. 30) ...	123T	Tungay, S. J. Acid-resisting iron and its uses in chemical plant. (London, Mar. 30) ...	87T
Seligman, R., and P. Williams. The inhibitory effects of water on the interaction of aluminium and (a) the fatty acids; (b) phenol, cresol, α - and β -naphthols; (c) methyl, ethyl, butyl, amyl, and benzyl alcohols. (London, June 15) ...	159T	Twiss, D. F. Discoloration of white paint. (Birmingham, June 29) ...	179T
Sharples, G. H. Notes on carbolic acid: application of phenol tests to works practice. (Glasgow, Apr. 15) ...	109T	Walls, E. Copartnership. (Annual Meeting, (Nov. 15) ...	301T
		Watson, C. E. See Babington, F. W. ...	257T
		Watson, E. R. Loss of indican during air-drying of indigo leaf. (Yorkshire, Mar. 15, May 15) ...	81T, 141T
		Weston, R. S. Recovery of potash from wool-scouring waste. (New York, Jan. 15) ...	17T
		Weyman, G. The relation between molecular structure and the activity towards hydrogen sulphide of oxide of iron. (Newcastle, Dec. 31) ...	333T
		Wheeler, E. The interconnection of economic botany and chemical industry. (Nov. 15) ...	307T

Journal of the Society of Chemical Industry

Vol. XXXVII · 1918

Name Index

N.B.—The Review, Transactions, and Abstracts Sections of the Journal are paged separately and are indicated by the letters R, T, and A respectively following the number of the page.

The letter (P) indicates that the matter referred to is a patent.

An asterisk appended to the number of a page indicates that the title only of an article is given, or in the case of patents, either the title only or the title and a reference to a previous patent.

The titles of new books are given within quotation marks.

A		PAGE
Abady, J. See Simmance, J. F.	490A*	
Abbott, W. G., jun. Evaporator (P)	454A	
Abbott Laboratories. See Burdick, A. S.	603A	
Abderhalden, E. and E. Eichwald. Glycerophosphoric acid; Synthesis of optically active —	782A	
Propyleneglycol and β -hydroxybutyric acid; Optically active —	782A	
Abeeking, K. Grey cast iron; Melting — in an oil-fired furnace	624A	
Abele, W. Paper: Process for decolorising waste — (P)	410A	
Abelmann, A. Trypaflavin solutions; Keeping properties of —	559A	
Ahererombic, R. G. Fermenting tun; Method and apparatus for preventing overflow of surface bubbles in a — (P)	190A	
Abraham, H. Roofing materials (P)	337A*	
Ach, L. See Meister, Lucius, u. Brüning	531A	
Achenbach, H. Sulphite-cellulose waste lyes; Purification of — by treatment with flue-gases (P)	764A	
Acheson, E. G. Defoeculating solid materials; Method of — (P)	2A*	
and Acheson Corporation. Defoeculating solid materials and agents therefor (P)	174A	
Acheson Corporation. See Acheson, E. G.	174A	
Actien-Gesellschaft für Anilinfabrikation. Acetic acid; Preparation of concentrated from dilute — (P)	370A	
Acridine dyestuffs of the benzene-naphthalene series and process for their manufacture (P)	236A	
Acridine series; Halogenated dyestuffs of the — (P)	235A	
Dyeings on vegetable fibres with diazotisable substantive dyestuffs; Process for developing — (P)	412A	
Sulphur dyes; Manufacture of — (P)	120A	
A.-G. für Antogene Aluminium Schweißung. Aluminium or its alloys; Autogenous welding of — (P)	739A	
Akt. Ges. der Chem. Produkten-Fabr. Pommersdorf, and R. Siegler. Fertiliser; Preparation of a phosphatic water-soluble — (P)	345A	
Akt. Ges. Cillander. See Klausner, O.	265A*	
Adam, W. G. Ammonia; Oxidation of — to oxides of nitrogen	179A	
Benzols, etc.; Analysis of crude —	50A	
Fractional distillation (P)	173A	
Separating crystals from solutions; Method of — (P)	399A	
Adams, A. Sugar cane; Extracting sucrose from — (P)	522A	
Adams, A. E. Hydrocarbon oils; Method of decolourising — (P)	683A	
Adams, J. W., and O. H. Erge. Mixing dry lime with liquids; Process and apparatus for — (P)	537A	
Adams, R., and O. Kamm. Dimethylglyoxime; Preparation of —	636A	
and others. Oxalyl chloride as a reagent in organic chemistry. Preparation of aromatic acid anhydrides. Reaction with alcohols	221A	
Adams, R. H., and H. Beatty. Butter substitute (P)	71A	
Adams, T. H. Aluminium alloys; Analysis of —. Discussion	94R	
Adamson, W. A. See Orndorff, W. R.	620A	
Addicks, L. Copper; Furnace refining of —	32A	
Addis, T., and A. E. Shevsky. Dextrose; Rate of production of colour in alkaline solutions of — and picrate	522A	
Addressograph Co. Stencil emulsions and paper stencils and their manufacture (P)	188A	
Adrian. Marine algæ; Use of certain — as fodder for horses	70A	
Adt, J. B. Drying apparatus (P)	197A	
Agcaoli, F. See Brill, H. C.	223A	
Agrestini, A. Cadmium and nickel; Alkali iodides as reagents for —	751A	
Aguilar, R. H. Linseed oil and lumbang oil; Comparison of — as paint vehicles	215A	
Ainsworth, W. A., and C. N. Mather. Dyeing machine; Winding and — (P)	621A	
L'Air Liquide. Air; Separation by liquefaction and rectification of elements of the — (P)	416A	
Air Reduction Co. See Kaufman, A.	333A	
Aitken, T. W. Crucible furnaces for melting metals (P)	518A	
Aitken, W. A. Paper-making and like machines; Felt driers for — (P)	146A	
Paper-making machine (P)	410A	
Paper-making machines; Suction-boxes of — (P)	687A	
Ajax Metal Co., and J. R. Wyatt. Electric induction furnaces (P)	340A*	
Akashi, K. Ink; Solid — (P)	313A	
Akers, H. G., and others. Malt product for bakers' use (P)	280A	
Aktiebolaget Carlit. Ammonium perchlorate explosives (P)	637A	
Ammonium perchlorate; Manufacture of — (P)	301A	
Aktiebolaget Cellulosa. Wood-cellulose; Process of producing soda-cellulose, particularly — (P)	651A	
Aktiebolaget Ingeniörsfirma F. Egnell. See under Egnell.		
Aktien-Gesellschaft. See under Actien-Gesellschaft		
Aktieselskapet Separator. See Holte, H.	165A*	
Alaska Products Co. See Cameron, F. K.	302A	
Albertsen, H. H. Tobacco; Process of treating — (P)	749A	
Albertson, R. W. See McCue, L.	167A	
Albrecht, E. W. Pumpkin seed oil; Manufacture of —	474A	
Alcock, F. H. Mercury fulminate and its determination; Discussion	148R	
Nitride formation; Studies in —. Discussion	109R	
White paint; Decoloration of —. Discussion	180R	
Works chemist and his relation to buying; The —. Discussion	109R	
Aldred, C. H. British Association of Chemists; Discussion on proposed formation of —	50R	
Aldrich, C. H. See Electrolytic Zinc Co.	518A	
Aldrich, T. B. Chloroetane (trichloro-tert.-butyl alcohol); Detecting small quantities of — in aqueous solutions	388A	
and Parke, Davis, and Co. Glandular extractive product; Manufacture of — (P)	560A

Subject Index

N.B.—The Review, Transactions, and Abstracts Sections of the Journal are paged separately and are indicated by the letters R, T, and A respectively following the number of the page.

The letter (P) indicates that the matter referred to is a patent.

An asterisk appended to the number of a page indicates that the title only of an article is given, or in the case of patents, either the title only or the title and a reference to a previous patent.

 α -Aminobutyric acid; Preparation of a mercury compound of —. (P) Löders ... 607a
 Amino-compounds; Benzoylation of aromatic —. Reverdin ... 715a
 -compounds; Preparation of — for foodstuffs, etc., by fermentation. (P) Eberle ... 190a*
p-Amino-N-methylformanilide; Manufacture of —. (P) Morgan ... 619a*
 Amino-nitrogen; Foam-inhibitor in the Van Slyke method of determining —. Mitchell and Eckstein ... 285a
 -nitrogen in pressed yeast manufacture. Schweizer ... 277a
p-Aminophenol derivatives; Estimation of — by hypochlorous acid. Powell ... 453a
 Electrolytic preparation of —. Shoji ... 459a
 Therapeutically valuable derivatives of —. (P) Soc. of Chem. Ind. in Basle ... 349a, 531a
 Ammonia, albuminoid; Determination of — in liquids containing gas liquor. Stephenson ... 439a
 Apparatus for catalytic oxidation of —. (P) Taliani ... 580a

	PAGE		PAGE
Ammonia—cont.		Ammoniac; Crude —. See Ammoniacal liquor.	
Apparatus for extracting — from coal gas. (P) Wilton, and Chemical Engineering and Wilton's Patent Furnace Co.	538A 232r	Ammoniacal liquor; Recovery of ammonium chloride from —, with extraction of cyanides and other valuable by-products. (P) Baker	88A, 766A
Catalytic synthesis of —. Maxted	1A, 360A*	liquor; Treatment of crude —. (P) Bonneau and Hasenfratz	150A*, 504A
compressors for refrigerating machines. (P) Apeldoornse Machiniefabr. en Metaalgieterij voor. Landaal	566A 207A	liquors; Analysis of —	35A
condenser for ice machines. (P) Maas, and Fricke Co.	435A	Ammonification in soils; Influence of chemical structure of compounds to be ammonified upon rate of —. Miyake	194R
control order, 1918	631A	Ammonium chloride; Effect of — on solubility of aniline in water. Wilsdon and others	362A
Correlation between production of carbon dioxide and accumulation of — by soil organisms. Neller	532A	Method of operating gas producers with recovery of —. (P) Riedel	517A
Determination of — in soil extracts and physiological solutions. Davison	314A	Production of — during working of blast-furnaces. (P) Riedel	88A, 766A
Determination of — in urine, serum, etc. Wiessmann	504A 299R	Recovery of — from ammoniacal liquor, with extraction of cyanides and other valuable by-products. (P) Baker	306R
Determination of — in used tannery lime liquors. Thompson and Suzuki	465A	works; Report on — by the Alkali Works' Inspector	16A
Determination of — by weighing as ammonium chloride. Villiers	54A	Ammonium citrate solutions; Preparation of neutral —. Shuey	673A
Effect of acetylene on oxidation of — to nitric acid. Taylor and Capps	621A	Ammonium molybdate; Recovery of molybdenum as — from residues. Malowan	344A 146R
Effect of hydrogen chloride on the synthesis of — from nitrogen and hydrogen. Ludlam	10A	Ammonium nitrate; Comparison of — with ammonium sulphate as a fertiliser. Schloesing, fls.	242A*
Formation of — by heating coke with calcium hydroxide. Glaser	759A	Field experiments with —. Hendrick	385A
leaching of copper tailings at Kenecott, Alaska. Lawrence	94R, 179A	Manufacture of —. (P) Blom, and Norsk Hydro-Elektrisk Kvaeststofaktieselskab	556A
Liquid purification of coal gas with simultaneous recovery of sulphur and —. Parrish	319R, 452R 28A	Treatment of —. (P) Berge and others	385A
liquor; Apparatus for manufacture of concentrated —. Greaves	29A	(P) Norsk Hydro-Elektrisk Kvaeststofaktieselskab	556A
liquor; Commercial concentrated — and its impurities. Colman and Yeoman	230R	Ammonium perchlorate explosives. (P) Aktiebolaget Carlit	637A
liquor; Manufacture of concentrated —. Parrish	242A*	perchlorate; Manufacture of —. (P) Aktiebolaget Carlit	301A 580A
liquor; Manufacture of concentrated and pure —. Hebdon	546A*	(P) Given, and Atlas Powder Co.	607A
liquor; Sources of loss during manufacture of concentrated —. Marsden	415A	persulphate; Effect of iron content of — on its photographic reducing power. Sheppard	252A 691A
Manufacture of —. (P) Classen	334A	phosphate; Availability studies with — and its chemical and biological effects on the soil. Allison	415A
(P) Devaucelle and Bensa	148A	phosphate; Process of obtaining —. (P) Cameron phosphates; Manufacture of mono- and di- —. (P) Hechenbleikner, and Southern Electro-Chemical Co.	744A
(P) Hershman, and Armour Fertilizer Works	405A, 458A*	potassium nitrate, a new top-dressing for sugar-beet. Hoffmann	521A
Manufacture of concentrated — from gas liquor. (P) Still	581A	Ammonium sulphate; Availability of nitrogen in — and other manures. Lipman and Blair	344A 498A
Manufacture of nitric acid from —. (P) Wells, and Ellis-Foster Co.	56A	Comparison of — with ammonium nitrate as a fertiliser. Schloesing, fls.	253A
Manufacture of — or of its salts by the direct recovery process. (P) Oré	75r	Direct process of making — in gasworks	241A
Manufacture of synthetic —. (P) Ellis and Lutkins	180R 320R 337A 179A	Effect of — in nutrient solution on the growth of soy beans in sand cultures. Wolkoff	744A
Manufacture of — from tobacco waste. (P) Zilk, and Odorless Fertilizer Manufacturing Co.	368A	and Glauber's salt; Production and separation of —. (P) Dawson	30A 466A 467A*
Mariate of —. See Ammonium chloride.	54A	Influence of — upon the germination and growth of barley in sand and soil cultures. Wolkoff	545A
Nephelometric estimation of —. Kober	730A 303A*	Manufacture of —. (P) Evans, and South Metropolitan Gas Co.	622A*
Operation of the Haber process for the synthesis of — in the United Kingdom	433R	(P) Fujiyama	436A 293A
Oxidation of — to oxides of nitrogen. Adam	402A	Manufacture of neutral —. (P) Capron	252A
Oxidation of —, Partington	291A	Manufacture of — and of sodium carbonate from sodium bisulphate. (P) Soo, Ind. de Prod. Chim.	29A, 123A
Oxidation of — to oxides of platinum and of rhodium. Wenger and Urfer	682A 234A	Oxidising ammonium sulphite to —. (P) Dancel and others	577A
oxidation process; Analytical control of the —. Taylor and Davis	412A	Preventing agglomeration and hardening of — during storage. (P) Dahl	577A 577A
oxidation and similar reactions; Starting and stability phenomena of —. Lilienroth	229A	Recovery of — from producer gas. (P) Mellor	306R
Purifying —. (P) Badische Anilin u. Soda Fabrik pyridine mixtures; Titration of —. Pridoux	81A	Significance of the sulphur in — applied to certain soils. Lipman and Gericke	622A*
recovery plant of coke-ovens; Effluents from —. Marsson and Weldert	31R, 41r 400A	sodium sulphate, and water; Equilibria in the ternary system —. Matignon and Meyer	159r
recovery plants in connection with coke-ovens; Chemical problems at —. Phillipson	638A	Utilisation of nitre cake for production of —. Dawson	127A 399R
recovery producer gas process and apparatus. (P) Lyman and Rambush	9R 71R	Amsterdam; Trade of — in 1917	530A
recovery at tar-distilling plants. Woodward	149A 241A 368A 105r, 234r	Amyl acetate; Manufacture of — from petroleum pentane. Brooks and others	783A
Reduction of nitrogen oxides to —. Guye and Schneider	128R	Separation of — from chlorohydrocarbons. (P) Oberfell and others	
Relation between the purity of — and the efficiency of refrigerating plants. Frerichs	457A	Amyl alcohol; Inhibitory effects of water on interaction of aluminium and —. Seligman and Williams	
Removal of — from gases. (P) Bradley and Schmidt			
and its salts; Rapid estimation of pyridine in —. Harvey and Sparks			
Separating — from gaseous mixtures. (P) Beck			
Separation and estimation of lower alkylamines in presence of —. Weber and Wilson			
soda. See under Soda.			
Sulphate of —. See Ammonium sulphate.			
Synthesis of —. Ludlam			
Maxted			
(P) Schmidt, and International Precipitation Co.			
(P) Starke			
Synthesis of — at high temperatures. Maxted			
Thermal synthesis of —. Maxted			
Validity of the patents of the Badische Anilin und Soda Fabrik for the production of synthetic —. Matignon			
Washer-scrubbers for extracting — from coal gas. (P) Spencer			

	PAGE		PAGE
Amylase; Nitrogenous substances which increase the activity of —. Rockwood	67A	Anthracene dyestuffs—cont.	
Anæsthetic bodies:		Manufacture of golden-orange vat —. (P) Chem. Fabr. Griesheim-Elektron	365A
(P) Parke, Davis, and Co., and Thorp	193A*	Manufacture of nitrogenous vat —. (P) Chem. Fabr. Griesheim-Elektron	365A
(P) Parke, Davis, and Co., and others	167A*, 193A*, 223A*	Manufacture of vat —. (P) Badische Anilin und Soda Fabrik	502A*
Anæsthetics, local; Preparation of substances for use as —. (P) Nagai	531A	(P) Wedekind and Co.	408A*
Analysis; Applications of magneto-chemistry to —. Quartaroli	750A	1,2-Phthaloylhydride series; Dyestuffs of the —. Ullmann and Dooson	178A
Chemical standards and their bearing on the unification of —. Ridsdale and Ridsdale	451A	Pyranthrindone, Scholl and Dischendorfer	364A
Graphic methods of —. Gradenwitz	392A	Pyranthrindone; Manufacture of —. (P) Scholl	764A
Gravimetric; Contributions to —. Winkler	390A	Anthracite culm; Utilisation of —	302A
Gravimetric; Time as a factor in —. Karaoglanow	352A	as reducing agent for zinc ores. Muhlhauser	423A
micro; Quantitative —. Reichard	40A	Transforming — into a product suitable for the manufacture of carbon electrodes by heating in an electric furnace. (P) Sienrin	706A
New process of quantitative —. Leme	257A	Anthraquinone; Determination of —. Lewis	459A
Qualitative — without use of hydrogen sulphide. Almqvist	561A	-fluorenone series; Rearrangement reactions in the —. Scharschmidt and Herzenberg	763A
Use of different alkalis in quantitative —. Palet	167A	Anthraquinone-neridonone dyes. See 1,2-Phthaloylhydride dyes under Anthracene dyestuffs.	
Use of textile fibres in microscopic qualitative chemical —. Charnot and Cole	21A, 75A	Anthraquinonesulphonio acids; Manufacture of salts of —. (P) Griffin, and The Barrett Co.	296A
volumetric; Apparatus for measurement of gases in —. Fincke	608A	Anthrax; Methods of immunisation against symptomatic —. Kelsor	671A
Analytical results; Calculation of —. Grossfeld	608A	toxin; Concentration of symptomatic —. Berg	671A
Andropogon sorghum hay; Composition and digestibility of —. Gaessler and McCandlish	602A	Anti-cathode. (P) Kelly	178A
Anemometers. (P) South Metropolitan Gas Co., and others	22A	Antigene for tubercle bacilli; Preparation of —. (P) Momoso	108A
Anemometry; Hot wire —; its principles and applications. Thomas	165r, 196A	Antigua; Sisal cultivation in —.	154A
Angler-fish liver oil. See under Oils, Fatty.		Tariff alterations	185n
Angola; Coal and petroleum in —	58B	Antimony; Chemotherapeutics of —. Tsuzuki	282A
Anhydrides; Preparation of aromatic acid —. Adams and others	221A	Determination of lead as phosphate and its separation from —. Vortmann and Bader	211A
Anhydrite; Hydration of —. Gill	585A	Determination of — in white metal. Kaiser	627A
Anhydropranol salts related to isobrazilein; Synthesis of —. Crabtree and Robinson	763A	Electrolytic refining of —. Wong	737A
Aniline; Effect of ammonium, sodium, and lithium chlorides on solubility of — in water. Wilsdon and others	194A	Extraction of — from low-grade ores. Wong	737A
-reducer. (P) Stevens, and Stevens Bros.	572A	-lead ore from Dumfries. Smith and Prior	435A
Separation of monomethylaniline, dimethylaniline, ethylaniline, or diethylaniline from —. Price	84r	Metallurgy of —. Schoeller	183A
Aniline Black; Production of — upon vegetable fibres:		production in 1916	418n
(P) Calico Printers' Assoc., and Fourmenaux	204A, 367A, 463A, 576A	production in China	343r
(P) Fourmenaux	652A*	Production of electrolytic — from impure ores. Borr	11A
Steamed —. Bechtel	462A	Pure —. Groschuff	648A
Animal oils. See under Oils, Fatty.		and selenium; Metallographic investigation of the system —. Chikashigi and Fujita	153A
Anions; Detection of —. Feigl	444A	-tin-lead alloys. Ellis	112n, 246A
Anatto dyes; West Indian	203B	in the Transvaal. Galbreath	626A
Annealing furnaces. (P) Foltz	309A	Antimony dioxide. Von Sailagyi	205A
furnaces; Continuous —. (P) Gibbons Bros., and Van Marle	473A	oxide pigments; Manufacture of white —. (P) Morris and Nevill	742A
furnaces; Means for moving articles through —. (P) Greenwood and Batley, and Clegg	740A*	sulphide; Electrochemical production of — from ores. (P) Griffin	212A
glass, porcelain, metals, etc., and apparatus used therein. (P) Hilger, Ltd., and Twyman	242A	tri-iodide; New metastable form of —. Vourasos	240A
metal articles; Scaling and —. (P) Perry, and Metalloids, Ltd.	428A*	vermillion; Manufacture of —. (P) Morris and Nevill	313A
metal wire by electricity. (P) Alexander and others	589A	Antineuritic and antiscorbutic factors; Differential behaviour of — towards adsorbents. Harden and Zilva	483A
of tools with sharp edges. (P) Pfirtzschner	379A	properties of infusorial earth extract of hydrolysed extract of rice polishings. Brill	164A
Annual Meeting; Proceedings of the thirty-seventh — at Bristol	203r	substance in wheat, rice, and maize grains; Distribution of the —. Chick and Hume	17A
Anode connector. (B) Gillis, and British American Nickel Corporation	553A	substances; Non-occurrence of — in beer. Harden and Zilva	524A
Anodes. (P) Swartley, jun., and Davis-Bourbonville Co. Electrolytic —. (P) Electrolytic Zinc Co., and Stuart	381A	substances; Preparation of — from carrots and yeast. Sugimura	748A
Anthocyanidins; Production of —. Everest	407A	Anti-pneumococcal serum; Phenols as preservatives of —. Voegtlin	714A
Anthocyanine; Production of —. Everest	407A	Anti-priming devices for evaporators, steam generators, steam separators, or like apparatus. (P) Fny	289A
Anthracene derivative; Manufacture of an —. (P) Scholl	764A	Antipyrine; Selenium derivatives of —. Von Konek and Schleifer	560A
oil; Washing of illuminating gas with —. Raffo and Scagliarini	143A	Antiscorbutic and antineuritic factors; Differential behaviour of — towards adsorbents. Harden and Zilva	483A
Oxidation of —. (P) Selden Co., and Gibbs	684A	property of desiccated and cooked vegetables. Givena and Cohen	746A
Anthracene dyestuffs:		substances; Non-occurrence of — in beer. Harden and Zilva	524A
Alizarin; Action of potassium ferricyanide on — in alkaline solution. Scholl and Zinke	763A	Antiseptic agents for use in preservative treatment of meat. (P) Sherman	135A, 634A*
Benzanthrone; New synthesis of —. Scharschmidt and Georgeneopol	573A	composition; Tetra-iodohexamethylenetetramine —. (P) Falk and others	670A
Scharschmidt and Korten	573A	dressing. (P) Walkey	559A
Flavanthrone; Synthesis of —. Scholl and Dischendorfer	364A	solution; The Dakin or Carrel-Dakin hypochlorite —. Griffith	19A
Indanthrene dyestuffs; Printing coloured reserves with —. Haller	462A	tablet. (P) Rogers and Davis	670A
Pomernaz	462A	value of some essential oils. Cuvcl	388A
Indanthrene; Manufacture of —. (P) British Dyes, Ltd., and others	202A	Antisepsics; Work on — done for Medical Research Committee, in the Pathological Department, Edinburgh University. Retlie	23r
Manufacture of —. (P) Badische Anilin und Soda Fabr.	764A*	Antitoxic sera; Concentration of — by salting-out the heat-denatured serum proteins with sodium chloride. Homer	748A
Manufacture of bluish-green vat —. (P) Badische Anilin und Soda Fabr.	145A*	sera; Influence of phenol and cresol on the concentration of — by the Banzhaf (1913) process. Homer	107A

Changes caused by — in nitrogenous constituents of milk. Supplee	667a
destruction by pressure; Method of —. (P) Witzel, and Food Sterilization Co.	604a
indole-forming; Detection of — in water by the bile-dextrose and phenol methods. Bourdet	603a
lactic; Influence of products of proteolysis of yeast on development of —. Vansteenberghe	103a
lactic; Process for compounding — with an enveloping protective medium. (P) Harris and others	319a 134a
lactic; Proteolytic activity of —. Gorini	777a
legume-infecting; Examination of commercial cultures of —. Follera	777a
for legume inoculation; Tests of commercial cultures of —. Noyes and Cromer	344a
nitrifying; Effect of — on solubility of tricalcium phosphate. Kelley	596a
nitrifying; Influence of — on phosphates. Hopkins and Whiting	743a
nitrogen-assimilating; Influence of reaction on —. Fred and Davenport	159a
nitrogen-fixing; Physiology and biology of —. Omeliansky	221a
pathogenic; Disinfectant action of quinine alkaloids on —. Bieling	436a
Potassium requirements of —. Koch	162a
Preparation of urease from —. Jacoby	189a
of soils; Influence of nitrates on nitrogen-assimilating —. Hills	746a
Bacterial precipitins, and detection of <i>B. botulinus</i> in preserved foods by the thermo-precipitation method. Bornand	133a
product; Manufacture of — for use as fertiliser. (P) Earp-Thomson	320a
Bactericidal properties conferred on the blood by intravenous injection of diaminoacridine sulphate. Browning and Galbraith	597a
Bacterio-toxins in the soil; Non-persistence of —. Hutchinson and Thaysen	746a
<i>B. botulinus</i> ; Detection of — in preserved foods by the thermo-precipitation method. Bornand	103a, 103a
<i>Bact. coli. communis</i> ; Enzymes concerned in decomposition of dextrose and mannitol by —. Grey	743a
<i>Bacterium lactis viscosum</i> ; Occurrence of — in soil. Fellers	255a
<i>Bacterium termo</i> in wort and beer. Petit	41a
Baddeleyite; Use of phenylnitrosodihydroxylamine-ammonium in the analysis of —. Brown	289a
Baffle-plates for evaporators, steam generators, steam separators, or like apparatus. (P) Fny	

Bagasse; Process of preserving — and making fuel therefrom. (P) Geveke	317a
Treating — to recover its value. (P) Marsden, and Sugar Cane By-Products Co.	523a
Baghouses for zinc oxide. Cregan	547a
Bags; Waterproofing — and rendering them impervious to dust. (P) Gadsden	45a, 262a*
Bahamas; Trade of —	122a
Bakeries; Alcohol as a by-product of —	363a
Baking powder:	
(P) Elkan Erben Ges.	347a
(P) Peter, and Royal Baking Powder Co.	528a
powder; Determination of carbon dioxide in —. Schellbach and Bodious	527a
Baku oilfields	380a
Balance; Convenient arrangement by illuminating a chemical —. Porritt	85r, 142r
Balata; Determination of resin and impurity in —. Dekker	341a
Oxidation of —. Peachey and Leon	56r
Ball-mills:	
(P) Candiot	643a
(P) Fairchild	613a
Balsam, Canada; Use of — in optical work. French of tolu; Evaluation of —. Cocking and Kettle	151a 486a
Baouba fibre for bag-making	152a
must; Alcoholic fermentation of —. Perratti and Riviera	524a 746a
Nutritive value of the —. Sugiura and Benedict	9r
Barbados; Prospective oilfields of —. Crnig	80r
Barbituric acid derivatives scheduled as poisons	
Barium; Determination of strontium in presence of — by means of calcium sulphate. Raikow	444a
Gravimetric determination of — as barium sulphate. Karaoglanow	108a, 168a
Separation and determination of strontium and —. Gooch and Soderman	719a 150r
and strontium; Separation of —. Waddell	150a, 561a
Volumetric determination of —. Waddell	
Barium carbonate; British market for American — chloride; Manufacture of —. (P) Dolbear and Bockman	287r 766a
chromate; Solubility of — in various aqueous solutions. Waddell	561a
disilicate; Crystals of — in optical glass. Bowen hydroxide; Manufacture of —: (P) Deguide	30a 30a*
(P) Deguide and Marhais	124a
(P) Penock, and Larowe Construction Co. nitrate; Manufacture of hydrogen peroxide and —. (P) Cobellis	622a
oxide; Manufacture of —. (P) Peacock, and Larowe Construction Co.	124a
sulphate; Gravimetric determination of sulphuric acid and of barium as —. Karaoglanow	108a, 168a
sulphate; Hydrated forms of —. Tingle	275a
sulphate; Time as a factor in the precipitation of —. Karaoglanow	352a
sulphide; Electrical reduction process for making (P) Fulton, and Metallurgical Laboratories, Inc.	545a 242a
sulphide; Purifying —. (P) Prisk and Harrison	
Bark, spent; Manufacture of waterproof fibrous composition from —. (P) Wallin and Hepbes	367a
Barley; Determination of acidity in — by titration in stages. Reichard	523a
Determination of starch in —. Kutze	317a
Dietary qualities of —. Steenbock and others	526a
Influence of ammonium sulphate on the germination and growth of — in sand and soil cultures. Wolkoff	744a
Institute of Brewing method for determination of moisture content of —	523a
Raw — as brewing material. Petit	102a
Barwood; Colouring matters of —. O'Neill and Perkin	235a
Baryta-alumina-silica mixtures; Deformation study of —. Watts	512a
glazes. Fritz	584a
as substitute for soda in water purification. Hundeshagen	670a, 713a
Bases; Manufacture of hydrogenised isocyclic or heterocyclic aromatic —. (P) Bayer and Co. organic; Phosphotungstates of certain —. Drummond	487a 485a
Basic refractory materials; Manufacture of —. (P) Stowe	31a*
Basing shark liver oil. See under Oils, Fatty.	
<i>Bassia longifolia</i> seed; Saponins from —. Spiegel and Meyer	388a 96r
Bauxite in British Guiana	335a
Corindite, a new refractory and abrasive material from —. Bigot	371a
Method for preliminary treatment of —. (P) Prager	57r, 363a
in the United States	

	PAGE		PAGE
Bavaria: Iron ore in —.	342R	Benzene; Detection of — in benzine. Formanek and others	329A
Beans; Mechanical retorts for destructive distillation of —. (P) Blair, Campbell, and McLean, and others	647A	Method of obtaining — from coal. (P) Pirani	365A
velvet; Composition of —.	394B	series; Manufacture of urcas and thioureas of the —. (P) Bayer and Co.	20A
Beating machines for making paper pulp. (P) Heys	544A*	Solidifying point of —. Formanek and others	329A
Beechnuts; Utilisation of — in Switzerland	459R	Sulphonation of —. (P) Downs, and The Barrett Co.	763A
Beef; Bromination of the products of hydrolysis of some proteins of —. Thrun and Trowbridge	387A	toluene, and xylenes; Commercial fractional separation of —. Butler and Popham	220R
Estimation of various forms of nitrogen in raw — including the products of hydrolysis of some of the proteins. Thrun and Trowbridge	387A	and total light oils in gases; Application of differential pressure method to determination of —. Davis and others	645A
Hexone bases of some proteins of —. Thrun and Trowbridge	387A	vapour; Determination of —. Anderson	83A
Beer; <i>Bacterium termo</i> in —. Petit	255A	vapour in gases; Differential pressure method for determination of —. Davis and Davis	644A
Brewing —. (P) Nathan	780A*	See also Benzol.	
Brewing — without malt. (P) Boulard	779A	Benzenesulphonic acid; Manufacture of — and of its alkali salts. (P) Aylsworth and others	296A
De-ionisation of iron in —. Reichard	218A	Benzidinesulphonic; Synthesis of some new substantive azo dyes derived from —. Ryan and others	763A
Determination of oxalic acid in —. Bau	524A	Benzine; Cleaning or washing clothes by means of —. (P) Steffen	621A
Distilling apparatus for separating alcohol from —. (P) Straus, and Baltimore Process Co.	*558A	Detection of aromatic hydrocarbons and unsaturated hydrocarbons in —. Formanek and others	329A
Influence of oxygen on the maltase-activity of yeast in —. Schönfeld and Krumhaar	161A	Examination of —. Formanek and others	329A
Influence of shaking on biological stability of —. Will	219A	Solidifying points of light, medium, and heavy —. Formanek and others	329A
Investigation of — for antineuritic and antiscorbutic potency. Harden and Zilva	524A	Benzoic acid and guaiacol; Physiological properties and medico-surgical applications of —. Menciére	72A
Manufacture of non-alcoholic malt —. (P) Block	633A	Manufacture of —. (P) Weston Chemical Co., and Savage	486A
Process of brewing non-intoxicating —. (P) Hadley	220A	Manufacture of paper containing —. (P) Elkan Erben Ges.	575A
rich in protein; Production of —. (P) Nathan Institut A.G.	346A	Use of benzaldehyde-sulphite compound as standard in separation and estimation of —. Geiger	715A
wort; Aeration and carbonation of — in connection with counter-current cooling apparatus. (P) Robinson	600A	Benzol; Apparatus for extracting — from coal gas. (P) Wilton, and Chemical Engineering and Wilton's Patent Furnace Co.	539A
wort; Artificial cooling of — in closed coolers, and elimination of gluten. Heintz	102A	Cleaning or washing clothes by means of —. (P) Steffen	621A
wort; <i>Bacterium termo</i> in —. Petit	255A	plant residues; Manufacture of resins from —. (P) Koppers Co., and Darrin	663A*
wort; Boiling of —. (P) Brauerer zum Wagnersbräu	746A	Process of purifying —. (P) Thompson	648A
wort; De-ionisation of iron in —. Reichard	218A	Production of — from Italian crude petroleum. Rodano	645A
wort; Means for heating and boiling —. (P) Robinson	190A	Purification of commercial — from thiophen and similar compounds. (P) Dutt and Hamer	540A
wort; Proximate constituents of sweet and hopped — at successive stages of the mashing process. Ling	162A	Purification of crude —. (P) Kipper	202A
wort; Physico-chemical investigations of —. Wöllmer	255A	recovery; Blue water-gas practice in conjunction with —. Keable	644A
wort; Utilisation of residues from Brunswick —. Reinke	557A	recovery from coal gas. Copp	726A
Beers; Attenuation of low-gravity —. Schlichting	524A	recovery of — from coke-oven gas. Wright	2A
Belgian mashing system suitable for light —. Johnson	778A	recovery plant operation; Laboratory methods for —. Sperr, jun.	2A, 26A, 50A
Decarbonising water used for diluting war —. Krumhaar	779A	Rectification of —. Hamer	173A, 295A
Iron sickness in this —. Windisch	779A	Removal of carbon bisulphide from crude —. Wilson	453R
Maladies of this —. Windisch	779A	Simple method of manufacturing crude —. Greaves	94B, 175A
Physico-chemical investigations of —. Wöllmer	255A	See also Benzene.	
Use of malt flour in production of English —. Hyde	162A	Benzols; Analysis of commercial "pure" —.	324R, 452R
Beeswax; Indian —.	379R	Analysis of crude —. Adam	50A
Manufacture of a product from —. (P) Holliday, and Holliday Chemical Co.	432A	Comparative values of coke-oven crude —. Haigh and Lamb	54R, 201A
Surgical dressing from —. (P) Holliday, and Holliday Chemical Co.	432A	Examination of —. Formanek and others	329A
from Ogawara (Bonin) Islands. Ueno	475A	Method for boiling point test of —. Sperr, jun.	26A
Beetling; Mechanical powdering of cotton fibre during —. Fort	121A	Benzotrichloride; Manufacture of —. (P) Gibbs and Geiger	52A
Beetroot; Balance of some constituent principles of the sugar — during the manufacture of sugar. Saillard	316A	Rapid analysis of mixtures of benzyl chloride, benzotrichloride, and —. Lubs and Clark	684A
Cultivation of the sugar — in the United Kingdom	55A, 77R, 249R	Benzoylation of some aromatic hydroxyl or amino compounds. Reverdin	715A
Possibilities of cultivation of sugar — in India. Potassium ammonium nitrate, a new top-dressing for —. Hoffmann	744A	N-γ-Benzoyloxypropyldihydrooregonidine ethyl ester, a new physiologically active substance from cocaine. Von Braun and Müller	281A
seed; Supplies of sugar —.	115R	O-Benzoyl-α-phenyl-β-diethylaminopropanol; Preparation of —. (P) Nagai	531A
slices; Process and apparatus for continuous extraction of —. (P) Eberhardt	745A	O-Benzoyl-α-phenyl-β-monoethylaminopropanol; Preparation of —. (P) Nagai	531A
Belgium. Export restrictions	479R	o-Benzoylsulphonamide; Determination of — in commercial saccharin from ammonia produced by acid hydrolysis. Richmond and Hill	246R
Import restrictions	479R	Benzyl alcohol; Inhibitory effects of water on interaction of aluminium and —. Seligman and Williams	159R
Iron ores of —.	342R	Benzyl chloride; Manufacture of —. (P) Gibbs and Geiger	52A
Belting; Textile — and method of preparing the same. (P) Buchner	53A	chloride, Manufacture of a difficultly soluble complex compound from dimethylaniline, zinc chloride, and —. (P) Chemical Works Rohner & Co.	202A
Benzal chloride; Manufacture of —. (P) Gibbs and Geiger	52A	Rapid analysis of mixtures of benzotrichloride, benzal chloride, and —. Lubs and Clark	684A
Rapid analysis of mixtures of — benzyl chloride, benzotrichloride, and —. Lubs and Clark	684A	p-Benzylphenyl carbonate. (P) Kropp, and Synthetic Patents Co.	223A
Benzaldehyde; Use of benzaldehyde-sulphite compound as standard in separation and estimation of —. Geiger	715A		
Benzaldehyde-sulphite compound; Use of — as standard in separation and estimation of benzaldehyde and benzoic acid. Geiger	715A		
Benzanthrone. See under Anthracene dyestuffs.			
Benzanthracene-carboxylic acid; Transformation of 1-phenylanthracene-2,3-dicarboxylic acid anhydride into —. Schnarschmidt and Korten	573A

Carbon monoxide— <i>cont.</i>		Carburising iron and steel articles. (P) Fennell, and British Carbonizing Co.	307A
Reaction between pure — and pure electrolytic iron below the Al inversion. Carpenter and Smith	585A	metals by acetylene. Hodgkinson	861
Recorder for estimating — in inflammable gases. Rideal and Taylor	453R	Carcaees; Apparatus for obtaining fat from animal —. (P) Zwicky	603A
Reduction of sulphuric acid by —. Milbauer	464A	Cardboard food containers	378a
Carbon tetrachloride vapour; Analysis of molybdenum compounds by volatilisation in a current of —. Jannasch and Laubi	732A	Process for rendering — grease- and waterproof. (P) Buchbinder	575A
vapour; Analysis of tungsten compounds by volatilisation in a current of —. Jannasch and Leiste	732A	Carnosine and histidine; Relation between —. Baumann and Ingvaldsen	605A
Manufacture of — from carbon bisulphide and chlorine. (P) Baillio, and Isco Chemical Co.	349A	Synthesis of —. Baumann and Ingvaldsen	606A
Separating — from other compounds. (P) Baillio, and Isco Chemical Co.	349A	Carootite ores; Radium from —	320R
Use of — in analysis of vanadium compounds. Jannasch and Harwood	578A	Carotin; Occurrence of — in oils and vegetables. Oil	633A
Carbonaceous materials; Destructive distillation of —. (P) Perkin and West	285A	Carp oil. <i>See under</i> Fatty oils	
materials; Distillation of —. (P) Billbrough	145A	Carrel-Dakin hypochlorite antiseptic solution. Griffith	19A
materials; Retorts for distilling or carbonising —. (P) Bradley	728A	Carrots; Preparation of antioeuritic substances from —. Sugura	748A
materials; Separation of volatile products from solid —. (P) White	234A*	Carvacrol from the leaves of <i>Coleus amboinicus</i> , Lour. Wechnizen	783A
materials; Vertical retorts for distilling or carbonising —. (P) Walker and Bates	458A	Manufacture of — from spruce turpentine. (P) McKee	531A
matter; Apparatus for distilling —. (P) Perry substances; Apparatus for destructive distillation of —. (P) Wellington	201A	Carvone; Conversion of — into pulegenio acid. Wallach and Von Rechenberg	605A
substances; Destructive distillation of —. (P) Wellington	571A	<i>Caryodendron orinocense</i> seeds. Bacharach	553A
substances; Distillation of —. (P) Sutcliffe, and Pure Coal Briquettes, Ltd.	761A	Case-hardening. (P) Bamfield	658A
substances; Mechanical retorts for destructive distillation of —. (P) Blair, Campbell, and McLean, and others	761A	material. (P) Rodman, and Rodman Chemical Co. material; Process of making —. (P) Blaich, and Blaich Co.	552A
Carbonates and bicarbonates; Analysis of mixtures of —. Clarens	647A	metal articles. (P) York and Taylor	95A
Detection of carbon dioxide in the analysis of —. Stafford	504A	metals. (P) Shimer	589A
Determination of carbon dioxide in —. Von Horvath	299A	<i>See also under</i> Iron and Steel	772A
Manufacture of carbon dioxide from neutral or basic —. (P) Behrens	369A	Casein; Action of pancreatic enzymes on —. Sherman and Neun	526A
Use of litmus and phenolphthalein as indicators in determination of bicarbonates and —. Mestrezat	581A	Distinguishing between whey proteins and —. Luning and Tönus	15A
Volumetric determination of formic acid or formates in the presence of —. Tsiropoulos	444A	Effect of time of digestion on hydrolysis of — in presence of starch. McHargue	526A
Carbonating of distilled water. Patten and Mains	87A	of human milk. Bosworth and Giblin	164A
wort and other liquids in connection with counter-current cooling apparatus. (P) Robinson	320A	Manufacture of horny bodies, particularly of clear, transparent or translucent quality from —. (P) Kohner	535A
Carbone method of retting textile plants by microbiological action. Carbone and Tombolato	609A	Preparation of pure —. Van Slyke and Baker	15A
Carbonic acid; Apparatus for cleaning —. (P) Nathan	27A	Casting armour-plates; Method and apparatus for —. (P) Guthmann	526A
solution; Production of a stable —. (P) Rudolf, and Elkan Erben Ges.	546A*	metals and other substances in moulds. (P) Straus pottery and other like articles. (P) Allen and Ames	659A
<i>See also</i> Carbon dioxide.	71A	Caster beans in the Dominican Republic	272A*
Carbonic oxide. <i>See</i> Carbon monoxide.		beans in Siam	58A
Carbonisable materials; Distillation of —. (P) Pearce	56A*	lipase; Hydrolysis of certain Indian oils by —. Latwala	153B
Carbonising apparatus and process for peat; Wet coal: —. (P) Boorue	727A	oil. <i>See under</i> Oils, Fatty.	366B
coal: Marshall	2A	seed lipase; Action of acids on —. Kita	194A
Savage	679A	Catalase; Action of —. Jacoby	312A
West	26A	of bacteria. Jacoby	557A
coal and canal; Apparatus for —. (P) Key	761A	Catalysis; Contact —. Bancroft	667A
coal, carbonaceous and other materials; Retorts for —. (P) Bradley	728A	Contact —. Decomposition of ethyl alcohol. Engelder	173A
coal, carbonaceous and other materials; Vertical retorts for —. (P) Walker and Bates	458A	Direct transformation of acyl chlorides into nitriles by —. Mailhe	19A
of coal; Low-temperature —. Evans	212R	Influence of temperature and constitution on velocity of hydrolysis of esters by hydrogen ion —. Burki	748A
coal; Recovery of oil in —. Perkin	175A	New method of dehydration of oximes by —. Mailhe and De Godon	136A
coal; System of —. (P) Yeadon and Whitaker of coal; Thermal decomposition of some of the products of —. Whitaker, and Sydam, jun.	295A	New method of preparation of aliphatic nitriles by —. Mailhe	137A
Gas economies with special regard to —. Dickson a mixture of peat and pitch. (P) Anderson	455A	New method of preparation of nitriles by —. Mailhe and De Godon	137A
peat, sawdust, sweepings, and other waste organic matter. Galsaine and Hombert	680A	Preparation of the methylolindines by —. Mailhe and De Godon	234A
wood. (P) Tissier	263A	Preparation of mono- and dimethylaniline by —. Mailhe and De Godon	234A
wood in inclined retorts. Molin	363A	Production of chlorine and sodium sulphate by —. (P) Kipper	181A
Carbons; Baking-furnace for —. (P) Webner, and Isbell-Porter Co.	727A	Some technical applications of —. Armstrong	2561*
Decolorising —. <i>See under</i> Decolorising.	361A	Synthetic production of cyanides by —. (P) Starke	241A
Carborundum; Detection of — in abrasives. Peters refractories. Linbarger	114A	Catalyst-concentrate for hydrogenation of oils; Manufacture of a —. (P) Ellis	129A
Carboy hampers or crates. (P) Cowburn, and Cowburn and Cowpar	335A	Catalysts for hydrogenation of oils; Manufacture of —. (P) Dewar and others	520A*
Carboys; Stopper for —. (P) British Dyes, Ltd., and others	656A	(P) Ellis	129A, 129A, 594A
Two-wheeled hand-propelled vehicle to carry two —. (P) British Dyes, Ltd., and others	199A*	(P) Kinura	250A
Carburets of hydrogen. <i>See</i> Hydrocarbons.	454A*	(P) Richardson, and Swift and Co.	475A
	47A*	for hydrogenation of oils; Manufacture of — from metal salts. (P) Bremen-Besigheimer Oelfabriken	250A
		for hydrogenation of oils; Manufacture of metallic —. (P) Richardson	214A
		for hydrogenation processes; Manufacture of —. (P) Ellis	569A
		Influence of foreign substances on activity of —. Paul and Hertmann	579A

Catalysts—cont.

	PAGE
Manufacture of —:	
(P) Müller	767A
(P) Schwareman, and Kellogg Products, Inc.	758A
(P) Weber, and Roessler and Hasslacher Chemical Co.	158A
Manufacture of — from natural ores containing hydrated iron oxide, (P) Fritzweiler and others	506A
Nickel — (P) Badische Anilin u. Soda Fabr.	199A*
Nickel — suspended in oil, (P) Ellis	187A*
for the promotion of synthetic chemical reactions; Preparation of — (P) Lane	397A
for reduction or hydrogenation purposes; Manufacture of — (P) Soc. de Stéarinerie et Savonnerie de Lyon, and Berthou	431A
Technical applications of —, Cumming	433B
Catalytic agents. See Catalysts	
method for preparation of aromatic nitriles, Mailhe processes; Poisoning action of carbon monoxide in —, Maxted	74A 9A
reactions between gases and/or vapours; Means for carrying out —, (P) Roy, and Morson and Son	397A, 678A
reduction of organic halogen compounds, Rosenmund and Zetzsehe	442A
Cataphoresis of kaolin, clay, etc. Kondo	693A
Catechol; Occurrence of — on bark from plane trees, Von Lippmann	281A
Cathode; Anti- —, (P) Kelly	178A
device; Incandescent —, (P) Meikle, and General Electric Co.	540A
Cations of third and fourth groups; Petersen's method for qualitative separation of —, Bohn and Starck	488A
Cattle-feeding cake; Supplies of —	136A
feeding stuffs (Requisition) Order, 1918	59A
food from the chia plant, (P) Lomauitz and Joffe	13A
food; Production of — from spent grains, (P) Ulman	317A
food. See also Feeding-stuffs and Fodder	
Caustic liquors; Action of — on steel plates, Stromeyer	41B, 60A
potash. See Potassium hydroxide	
soda. See Sodium hydroxide	
Causticising sodium carbonate liquors, Griffin and others	28A
Cay-doe; Fatty oil from seeds of —, Heim	63A
Cay-gioc. See Cay-doe.	
Celebes; Iron-ore deposits in —	458A
Celestine deposits in Great Britain	202A
Celluloid; Analysis of —, Hervé	686A
Manufacture of — non-inflammable —, (P) Dreyfus	651A, 687A
Stabilisation of nitrocellulose for manufacture of —, Colassi	686A
substitutes; Process of making —, (P) Satow	27A
Cellulose, a German substitute for jute	203B
Cellulose; Apparatus for washing and airing —, (P) Berglund	296A
Boiler for treating — suspended in liquids, with steam, (P) Bock	409A
of cereal straw; Nature of —, Heuser and Haug	365A, 650A
-containing materials; Process of treating —, (P) Herbein	151A*
and its derivatives; Fluorescence of —, Lewis	542A
Determination of — in wood, Johnson and Hovey	132B
dextrose relationship; Re-investigation of the —, Cunningham	236A
Digesters for use in manufacture of —, (P) Schaufelberger	203A
Distillation of — in <i>vacuo</i> , Pictet and Sarasin	49A
Esparto — and the problems of constitution, Cross and Bevan	236A
film; Composite —, (P) Brandenberger, and Soc. La Cellophane	502A
industry; Use of <i>Sorghum vulgare</i> (millet) in the —, Hans	366A
Manufacture of coverings or masses of structureless —, (P) Cross, and Viscose Development Co.	461A
Manufacture of oxalic acid by direct oxidation of alkali fusions of substances containing —, (P) Mensen	466A
manufacture; Waste liquors from — as yeast foods, Bokorny	436A
Nitration of cotton — and influence of prolonged bleaching on its transformation into dinitrocellulose, Namias	167A
and nitrocelluloses, Hervé	718A
Process of dissolving —, (P) International Cellulose Co.	146A
production in Russia	141B
Scheme for analytical investigation of — prepared from vegetable fibrous materials, Schwalbe	685A
soda; Process of producing —, (P) Aktiebolaget Cellulosa	651A

Cellulose—cont.

Jordan and Hopkins	55a
Kremers and Balke	300a
Kremers and others	300a
Yntema and Hopkins	654a
rare; Carbides of — of cerium group. Daniels	732a
rare; Electrolysis of solutions of the —. Dennis and Ray	123a
rare; Mixture of sulphates of — as an insecticide. Appel	348a
Purifying precipitates of fluorides of —. (P) Burns, and National Carbon Co.	581a
East Africa Protectorate. Prohibited imports	100n, 384r
Eberth's bacilli; Search for — in water. Diérent and others	106a
Ebonite; Manufacture of plastic masses resembling — from yeast. (P) Blücher and Krause	478a
Eccaine, a new physiologically active substance from cocaine. Von Braun and Müller	281a
Echinocystis oreana seeds; Fatty oil from —. Daughters	187a
Economiser; Steam-boiler —, and method of operating it. (P) Jacobus, and Babcock and Wilcox Co.	198a

Ecuador. Prohibited exports	120n
Tariff alterations	62n
Edge runners. (P) Savage, and Brinjes and Goodwin, Ltd.	613a
Edinburgh University degrees	357r
Educution in different countries; Comparison of facilities for —. Hudfield	242n
Natural science in —. —	213n
Effluents from ammonia-recovery plant of coke-ovens. Marsson and Weldert	402a
containing organic matter in solution; Method of treating —. (P) Cummings, and Eastern Tanners Glue Co.	388a
Separation of grease from wool scouring or like —. (P) Jarmain	574a
Egg food preparations. (P) Cutler	528a
preservative. (P) Davis and Miccolino	164a
yolk; Hydrocephalin of —. Lavene and West	606a
yolks; Determination of fat in commercial —. Lamb and Harvey	314a
Eggs; Chemical and physical constants of the oily matter of —. Schaffer and Meyer	668a
Determination of loosely bound nitrogen in — as ammonia. Hendrickson and Swan	633a
Dried — in powder form. (P) Spence and Kemp	669a
Liquid ostrich —. —	225r
Method for making soluble the nucleo-albumins in preserved —. (P) Bendixen	387a
Photographic method for examination of —. Le Roy	279a
Recovering substances from fresh, decomposed, or partially decomposed —. (P) Hussey	713a
<i>Eichornia crassipes</i> as a source of potash. Day	631a
Value of — as fertiliser. Finlow and McLean	253a
<i>Elais poissonii</i>, a new species of oil palm. Fauchère	741a
Elastic mass; Manufacture of an —. (P) Ali-Cohen	775a*
Elastins in the tanning process. Moeller	434a
Elder seeds and berries; Fatty oils of —. Zellner	519a
Electric accumulator plates; Separators or non-conducting supports for —. (P) Leitner	519a
accumulators:	
(P) Chkliar	96a
(P) La Roche	706a
are deposition of metals; Metal electrode used in —. (P) Jones	474a*
are device; Enclosed —. (P) Clough, and General Electric Co.	50a
are lamp; Cadmium vapour —. Sand	241r
are lamps; Electrodes for —:	
(P) Edgecomb, and Specr Carbon Co.	571a
(P) Little, and Westinghouse Electric and Manufacturing Co.	648a
are-light electrodes containing luminescent substances. (P) Rütgerswerke A.G.	618a, 618a
are; Metal electrodes used in depositing and soldering by the —. (P) Jones	705a
are soldering; Electrodes for —. (P) Pesentore	628a, 706a*
ares; Melting refractory substances by —. (P) Webb	553a*
ares; Method of controlling and apparatus for producing —. (P) Constable, and Technicolor Motion Picture Corporation	4a
batteries:	
(P) Renner and others	213a
(P) Henry	33a
(P) Sokal	273a
batteries; Restoration of exhausted —. Stern	380a
battery cell; Secondary —. (P) Csanyi	773a
battery depolarisers; Manufacture of —:	
(P) Froeh and others	592a
(P) Holmes, and National Carbon Co.	593a
battery plate separators; Composition for —. (P) Becker	249a
cell; An experimental carbon —. Reed	311a
cell; Lead standard —. Henderson and Stegmann	179a
cell; A permanganate —. Warrington	186a
cell; Producer-gas —. Hofmann	765a
cells. (P) Conrad and Schoenmehl	339a
furnaces. See under Furnaces.	
heater for use in analytical distillation of gasoline. Dean	725a
heating; Pastenisation of saké by —. Tadokoro and others	68a
incandescence lamp having a copper leading wire. (P) Yaani and others	84a
incandescence lamps:	
(P) Blau, and General Electric Co.	571a
(P) Hamburger and others	234a
(P) Orange, and General Electric Co.	762a
incandescence lamps; Crystals in filament form as used in —. Schröter	363a
incandescence lamps; Manufacture of filaments for — composed of a solid solution of thorium in tungsten. (P) Pintsch A.G.	331a
incandescence lamps; Method of exhausting —. (P) Langmuir, and General Electric Co.	571a*
lamps; Leading-in conductors for —:	
(P) Fiak and others	571a*
(P) Jacoby, and General Electric Co.	458a*
(P) Van Keuren, and General Electric Co.	501a

Furnaces:	PAGE	Furnaces—cont	PAGE
(P) Ragot, and Stanley Works	678A	Electric —:—cont.	
(P) Hall	141A	(P) Moore	592A
(P) London Electric Supply Corporation, and Fox	2A*	(P) Nathusius	474A*, 593A*
(P) Moyer	400A	(P) Pewcock, and Haslup and Pewcock	773A
(P) Rulya and Bohstengel	555A	(P) Sahlin	381A
(P) Tierney, and American Shop Equipment Co.	557A	(P) Shield, and Armour Fertilizer Works	662A
(P) Van der Does de Bije	678A	(P) Snyder	186A
(P) Zulver and Smith	498A*	(P) Vom Baur	156A, 774A*
Annealing —. (P) Foltz	369A	Electric — for annealing and forging steel, Scott electric; Calcining coal at high temperatures in —. (P) Dyssen	682A
annealing; Continuous —. (P) Gibbons Bros., and Van Marle	473A	electric; Condensing gases containing phosphorus pentoxide and silicon fluoride from —. (P) Hechenbleikner, and Southern Electro-Chemical Co.	415A
for annealing, hardening, or heat treatment of metals, and the like. (P) Smallwood	771A	electric; Contact for —. (P) Snyder	592A
annealing; Means for moving articles through —. (P) Greenwood and Batley, and Clegg	740A*	electric; Control apparatus for —: (P) Keene, and General Electric Co.	213A
for annealing, tempering, or heat treatment of metals. (P) Hoyle and Burn	589A	(P) Seede, and General Electric Co.	156A
Apparatus for removing coke discharged from —. (P) Drakes, Ltd., and Drake	45A*	electric; Control and regulation of —. (P) Brown, Boveri, and Co., and Gray	249A
for baking carbon electrodes and for other purposes. (P) Wehner	429A*	electric; Device for closing orifices in roof and walls of — through which the electrodes pass. (P) Watson and Co. (of Sheffield), Ltd., and Travis	553A*
Baking — for carbons, etc. (P) Wehner, and Isbell-Porter Co.	114A	Electric — for distilling zinc. (P) Thomson, and Thomson Press Co.	590A
for baking earthenware. (P) Litinsky	467A	electric; Electric transformers for use in connection with —. (P) Bibby	214A*
Billet-heating and the like —. (P) Crowcroft and Morris	771A	electric; Electrode holders for —: (P) A./S. Arendal Smelteverk	707A*
Blast —: (P) Fisher	95A*	(P) Fischer	311A
(P) Foster	95A*	(P) Steinberg and Gramolin	774A*
(P) Wrightson and others	33A*	electric; Electrodes for —: (P) Hamilton and others	661A
blast; Bashes of —. (P) Foster	128A	(P) Nathusius	519A
blast; Charging apparatus for —: (P) Blast Furnaces and Equipment, Ltd., and Ritson	706A*	electric; Faraday Society discussion on —. Electric — for hardening steel or the like. (P) Wild and Barfield	154A
(P) Sahlin	339A*	Electric — of the heated coil type. (P) Kievits, and Kynoch, Ltd.	707A
blast; Coke as fuel for —. Hewson	32A, 60r	Electric heating —. (P) Walker and Cox	249A
blast; Copper tuyeres for —. Reece	304A	Electric — for heating non-ferrous metals. Miller Electric — for high temperatures. Ferguson and Morwin	546A
blast; Drying air for —. (P) Bradley and Schmidt	81A	electric; Holders or fittings for electrodes of —. (P) Hoyle and Fawcett	273A
blast; Elevators for —. (P) Munier et Cie	552A*	Electric induction —: (P) Ajax Metal Co., and Wyatt	340A*
blast; Enquiry on the working of — in the United Kingdom	303A	(P) Böckman	662A
blast; Fuel economy in —. Hutchinson	304A	Electric induction — for melting and refining metals. (P) Foley	308A
blast; Hoists for charging —. (P) Wrightson and others	33A*	Electric induction metallurgical —. (P) Turner	12A
blast; Hot blast for —. Simmersbach	515A	Electric — for making sodium cyanide. (P) Freeman, and American Cyanamid Co.	733A
blast; Hot-blast stoves used in connection with —. (P) Stein et Cie	272A	electric; Manufacture of ferro-alloys, e.g., ferro-manganese in —. Keeney	702A
blast; Importance of coke-hardness in —. Cochran	304A	electric; Manufacture of ferro-phosphorus in —. (P) Webster, and Gray, jun.	473A
Blast — and method of operating them. (P) Slick blast; Production of ammonium chloride during working of —. (P) Riedel	517A	electric; Manufacture of pig iron in — in war times. Turnbull	9A
blast; Proposed erection of — in Holland	322r	electric; Manufacture of steel in —. (P) Keller	247A
blast; Recovery of potash in operation of —. Chance	222r	electric; Manufacture of steel shoes and dies in — on the Witwatersrand. Stanley and Buchanan	32A
blast; Removing solid "metal bottoms" of —. (P) Riddle	93A	Electric — for manufacture of tungsten powder. (P) Insull	248A
blast; Slag control in iron — by means of slag viscosity tables. Feild	735A	Electric melting —. (P) Bailey and others	592A
blast; Treating ores in —. (P) Rasset	771A	Electric — for melting or refining non-ferrous alloys. (P) Faulkner	378A
blast; Water circulation of tuyeres and coolers of —. (P) Foster	13A*	Electric metallurgical —. (P) Buhl	186A
for calcining copper and like ores. (P) Squire	310A*	Electric metallurgical — and method of supplying current thereto. (P) Gray	740A
for calcining limestone, fireclay and other refractory materials. (P) Richards	373A	Electric — of new type for brass manufacture	278r
for chemical reactions. (P) Shield, and Armour Fertilizer Works	662A	Electric — in the Norwegian iron industry. Styri	10A
for combustion of pulverulent fuel. (P) Muhlfeld and Carneristi	83A	Electric ore —. (P) Ward and others	155A
and converters; Combined tilting and reversible open-hearth melting —. (P) Rollason	378A	electric; Phase distribution for —. (P) Bailey and others	312A
Crucible —: (P) Connolly	378A	electric; Polyphase —. (P) Dixon	62A
(P) Keith and Keith	473A	electric; Present status of brass melting in —. St. John	737A
(P) Lacey	518A	electric; Preventing oxidation or wasting of electrodes in —. (P) Hamilton and Holland	381A
(P) Whitlum	154A	Electric — for producing endothermic gas reactions. (P) Pfäehler and others	96A
Crucible and like —. (P) Gaunt and others	308A	electric; Production of metals in —. (P) Humbert	155A
crucible and like; Operating mechanism of tilting —. (P) Aldays and Onions Pneumatic Engineering Co., and others	519A*	Electric — for reduction of tungsten. (P) Pfannstiehl, and Pfannstiehl Co.	591A
crucible and like; Preheating the charge in —. (P) Gaunt and others	426A	electric; Re-melting of aluminium pig in —. (P) Miller	475A
Crucible melting —. (P) Harvey, and Morgan Crucible Co.	628A	Electric — for re-melting aluminium pig. Miller Electric resistance — for high temperatures. Rosenhain and Coad-Pryor	156A
Crucible melting — heated by gas or oil. Harvey, and Morgan Crucible Co.	590A	electric; Roasting — for melting brass. Gillett and Rhoads	423A
Crucible — for melting metals. (P) Aitken	518A	Electric — for sintering tungsten. (P) Pfannstiehl, and Pfannstiehl Co.	659A
Crucible melting — for glass. (P) Stein et Cie	8A	electric; Smelting of phosphate rock in — and use of the Cottrell precipitator in collecting the volatilised phosphoric acid. Carothers	87A
Design of — for combustion of coal. Kreislinger and others	328A	Electric smelting — in Sweden	364A
for drying, calcining, and sintering powdered ores, fine-dust, etc. (P) Schumacher	629A		
Electric —: (P) Booth-Hall Co.	592A		
(P) Collins, and General Electric Co.	592A		
(P) Dixon	273A*, 312A*		
(P) Filmer and Denton	96A		
(P) Graves and Etchells	273A*		

Furnaces—cont.

Electric — for steel melting. (P) Steinberg and Gramolia	61A
electric steel-melting; Firebrick from crown of —, Rees	699A
electric; Supply of energy to —. (P) Travis, and Watson and Co.	591A
electric; Temperature-controlling device for —. (P) Hearson	13A
electric; Three-phase — and method of operating them. (P) Snyder	773A
Electric — and transformers for use therewith. (P) British Electric Transformer Co., and Berry	380A
Electric — for transforming anthracite, coke, and other materials rich in carbon into a product suitable for the manufacture of carbon electrodes. (P) Sieurin	706A
electric; Treatment of gases in —. (P) Edwin, and Norsk Hydro-Elektrisk Kvaestofaktieselskab	381A
electric; Treatment of refractories in —. Hutton	698A
Electric tube — for reducing tungsten. (P) Pfanstiehl, and Pfanstiehl Co.	379A
electric; Water-jacket for electrodes for —. (P) Kitchen	187A*
Electrically heated resistance —. (P) Greaves and Ethells	428A
for enamelling metal articles. (P) Dupont	700A
Evaporating — for surface heating, particularly for concentrating acids. (P) Chem. Fabr. zu Schöningea, and Vetterlein	766A
Gas —. (P) Ionides, jun.	569A
Gas burners for —. (P) Fletcher, Russell, and Co., and others	177A
gas-fired; Apparatus for maintaining proportional delivery of gas and air to —. (P) Keith and Keith	756A
gas-fired; Burners for —. (P) Yates and others...	569A
Gas-fired — for heating and melting metals. (P) Hall	246A
Gas-fired — for heating tools and other articles. (P) Yates and others	739A
Gas-fired muffle and like —. (P) Simon-Carves, Ltd., and Brown	232A
Gas-fired — for pottery and other purposes. (P) Yates and others	89A
Gas-fired steel heating —. (P) Richmond Gas Stove and Meter Co., and Thompson	271A
Gas-heated	141A
(P) Wallwin	678A
Gas-heated and similar — for heat treatment of metals. (P) Yates and others	518A
Gas valves for steel smelting —. (P) Davies	272A*
Gaseous fuel —. (P) Ionides, jun.	219A
for generating heat. (P) Thomas and Mainwaring...	1A
for generating heat for steam raising or other suitable purposes. (P) Whitham	756A
Glass —. See under Glass.	
hand-fired; Low-rate combustion in fuel beds of —. Kreisinger and others	758A
hand-fired; Tars distilled from bituminous coal in —. Katz	762A
for heat treatment of metals. (P) Rogers and Walter Heating	589A
(P) Chantraine	454A*
(P) Lummis, and Morgan Construction Co....	772A
for heating air. (P) Garner and Posnett	496A*
for heating ingots. (P) Davis	308A
for heating metal articles and the like. (P) Southorne	739A
for heating metal sheets. (P) Thermic Plating Process Co., and Watkins	629A*
hot-blast; Operation of chequer brick heaters for —. (P) Pfoser and others	248A
Incinerating —. (P) Stokes	599A
Liquid-fuel —. (P) Yarrow	454A*
Manufacture of refractory bricks for —. (P) Reynolds	31A
Material conveyor for —. (P) Cram, and Railway Materials Co.	566A
Means for feeding goods into and removing goods from annealing and other —. (P) Gibbons Bros., and Van Marle	518A*
Mechanical feeders for —. (P) Harvey and Wright	176A
Melting —:	
(P) Fisher	309A
(P) Hall	128A
for melting brass and the like; Crucible —. (P) Price	569A
Metal heating, metallurgical, and analogous heating —. (P) Richmond Gas Stove and Meter Co., and Thompson	212A
Metallurgical —. (P) Wedge	61A
Metallurgical heating —. (P) Walker and others more especially intended for treatment of zinc. (P) Van Gulek	94A
Muffle —. (P) Steere	185A
oil; Burners for heavy oils for use in —. (P) Steurs	230A
Oil-fired —. (P) Halkett	3A
Oil-fired — for heating and melting metals. (P) Hall	114A
Oil-fired — for melting grey iron. Abeking	248A
	624A

Furnaces—cont.

Oil-gas and other gas —. (P) Burdons, Ltd., and others	358A
Open-hearth —. (P) Blair, jun., and Blair Engineering Co.	13A
open-hearth; Cooling interior of —. (P) Reichpietsch	628A
open-hearth; Method and apparatus for tapping —. (P) Smith	33A
open-hearth; Principles of design of —. Bagley	625A
open-hearth steel; Removing molten slag from — by means of air or steam blast. (P) Bagley	472A
open-hearth; Utilisation of waste heat from — for generation of steam. Mackenzie	625A
Operating — with recovery of heat. (P) Koppers, and Koppers Co.	48A
Ore roasting —. (P) Rowley and Merton	426A
oven; Application of coal gas as fuel in —. Hartley	66B
for production of illuminating gas in vertical retorts or chambers. (P) Chamottefabrik Thonberg A.-G.	682A
Puddling —. (P) Mackinlay	94A
Recuperator —. (P) Stabblebine	756A
Regenerative —. (P) August and Hooson	677A
Regenerative gas —. (P) Harvey Gas Furnace Co., and Harvey	456A
regenerative; Gas or air ports for —. (P) Rees, and South Durham Steel and Iron Co.	725A*
Regenerative gas heating —. (P) Topham	704A
Regenerative gas retort —. (P) Russell, and Parker-Russell Mining and Manufacturing Co.	143A
reverberatory copper; Fetting of —. Rutherford	547A
Roasting —. (P) Zavelberg	426A
roasting; Furnace rakes for mechanical —. (P) Brand	518A
roasting; Mechanical —:	
(P) Bingham	659A
(P) Ramen	659A
for roasting ores. (P) Harbord	309A
roasting; Rabble-arms for mechanical —. (P) Huntington, Heberlein, and Co., and Bingham	629A*
for roasting zinc blende. Chase	11A
Shaft — for burning cement, lime, and similar materials. (P) Steiger and Steiger	374A
shaft; Method and apparatus for charging —. (P) Würth	495A
Shaft for roasting —. (P) Baird, and General Chemical Co.	339A
Smelting —:	
(P) Gaunt and others	659A
(P) Llopert, and Mineral Refining and Chemical Corporation	154A
(P) Lundberg	740A*
(P) Stevenson	550A
for smelting metals, etc.; Manufacture of refractory bricks, blocks, tuyères, etc., for use in —. (P) Mason and Couper	700A
Smelting and refining —. (P) Martin	551A
for smelting and refining metallic swarf and the like. (P) Tylor and Sons, and others	739A
Steel-making —. (P) Wellman, Seaver, and Head, and Smith	771A
steel; Removing solid "metal bottoms" of —. (P) Riddle	93A
Tank — for white glass fired by gas from a coke-producer. Roxburgh	133B, 242A
Tilting crucible —. (P) Gaunt and others	518A
for treating certain mineral and chemical products. (P) Leyes	498A
for treating ores. (P) Tanzer	94A
for treating zinc. (P) Van Gulek	773A*
Tunnel —. (P) Brand	700A
Zinc-extracting — with vertical retorts. (P) Von Zelewski	95A
Zinc oxide —. Cregan	11A
Fusion apparatus. Pope	81A

(P) Jefferies, and Morgan Construction Co.	144A, 200A
(P) Lummis and others	117A
(P) Lyman and Rambush	682A
(P) Siemens	362A
(P) Stewart	176A
(P) Taylor, and General Chemical Co.	646A
(P) Thuman	143A
(P) Wollaston	49A, 176A, 233A
producers: Apparatus for feeding and distributing fuel to —. (P) Thuman	456A
producers: Apparatus for feeding fuel to —. (P) Bentley and Appleby	500A
producers: Charging and poking mechanism for —. (P) Owens, and Toledo Glass Co.	569A
producers: Comparison of coke and coal as fuel for —. Studdler	615A
producers: Comparison of — from which slag is tapped off with those of water-seal type. Markgraf	498A
producers: Construction of —. (P) Bartlett	456A
producers: Control of —. (P) Riedel	727A
producers: Feeding mechanism for —. (P) Lummis, and Morgan Construction Co.	529A, 646A
producers or the like: Automatic removal of ashes from —. (P) Bentley and Appleby	501A*
producers and the like: Open-hearth —. (P) Dowson and Mason Gas Plant Co., and Webb	646A
producers: Mechanical feeders for —. (P) Harvey and Wright	176A
producers: Method for operating — with recovery of ammonium chloride. (P) Riedel	362A
producers: Operation of — with previous drying of moist fuels. (P) Eckardt	350A, 570A
producers: Steam and air mixer for —. (P) Logan	144A
producers: Suction —. (P) Schneidewind	457A
producers: Vaporising apparatus of —. (P) Le Gaz Pauvre Economique	500A
producers with arrangement for removing coke. (P) North Kommandit-Ges.	457A
producing and consuming plants. (P) Dreffein and Flinn	293A
purification masses: Analysis of spent —. Müller	690A
purification: Oxide —. Tindale	402A
purifiers: Purifier grids and means for supporting them in —. (P) Spencer	405A*
-purifying apparatus. (P) Cheney and Reynolds	330A
-purifying material: Analysis of spent —. Wentzel quality: Standards for — and toluol recovery. McBride	653A, 174A
reactions: Electric furnaces for producing endothermic —. (P) Pfahler and others	96A
reactions: Method of obtaining general velocity curves for complete homogeneous — at constant pressure. Todd	289A
Recovering oil and — from oil-bearing strata. (P) Squires and Smires	49A
Recovery of cyanogen-bearing compounds from coal —. (P) Epenhahn	570A
Recovery of light oils from —. (P) Parker, and Societ-Solvay Co.	177A
Relative efficiency in use of different grades and compositions of —.	681A
residuals: Prices for —.	283B
Restriction and Motor Spirit (Consolidation) Order, 1918	39B

retort furnace: Regenerative —. (P) Russell, and Parker-Russell Mining and Manufacturing Co.	143A
retort settings: Horizontal and inclined —. (P) Dempster and Sons, and Brooke	646A
retort settings: Regenerative —. (P) Drakes, Ltd., and Drake	293A
retorts: Construction of vertical —. (P) Toogood, and Dempster and Sons	363A*
retorts and generator plants: Operation of coal —. (P) Strache	570A
retorts: Heating flues of —. (P) Simpson	682A
retorts and methods of working them. (P) West	233A
retorts: Production of water-gas in continuous vertical —. Balsam	143A
retorts: Steaming horizontal —. Rew	329A
retorts. See also under Retorts.	
Separating liquefiable constituents from —. (P) Peterson, and Consolidated Liquid Gas Co.	501A, 186B
Supply and employment of — in flexible containers testing apparatus. (P) Webster	168A*
traction: Appointment of sub-committee on —. Traction Committee of H.M. Petroleum Executive; Interim report of —.	251B, 186B
Treatment of sewage for the production of combustible —. (P) Flicker	38A
under compression: Approved uses of — during the war period	186B
Valves for controlling, reversing, and by-passing the flow of — through purifiers, condensers, and the like. (P) Dempster and Sons, and others	405A
Vertical retorts for production of illuminating —. (P) Birkholz	456A
warfare	320B
warfare: Enemy methods of —. Auld	127B
wash boxes: (P) Chrisman	262A
(P) Chrisman, and United Gas Improvement Co.	501A*
washer. (P) Dreffein	500A
washer-scrubbers: (P) Crisfield	233A
(P) Crisfield, and United Gas Improvement Co.	406A*
Washer-scrubbers for extracting ammonia, naphtha, and other impurities from coal —. (P) Spencer	457A
Washing of illuminating — with anthracene oil. Raffo and Scagliarini	143A
water: Adaptation of twin generator gas plants to manufacture of — containing varying proportions of the component gases. (P) Smith, and Perry and Co. (Bow), Ltd.	456A
water: Apparatus for production of —. (P) Soc. d'Exploit des Appareils Rateau	404A
water: Manufacture of fuel from coal screenings and by-product from manufacture of —.	364B
water: Manufacture of — as substitute for natural gas. (P) Palmer	500A
water: Production of carburetted —. (P) Heyl	48A
water: Production of — in continuous vertical retorts. Balsam	143A
water: Theory of formation of —. Gwosdz	538A
water: Use of blue — in conjunction with benzol recovery. Keable	644A
from wood and peat	281B
works construction and practice: Modern developments in —. Meade	112B
works: Direct process of making ammonium sulphate in —.	49B
Works (Ministry of Munitions) Order, 1918	267B
works: Treatment of refuse from —. (P) Wellington and Etherton	49A
Gaseous combustion. (P) Ionides, jun.	571A
fuel: Apparatus for producing —. (P) Rose	144A
fuel furnaces. (P) Ionides, jun.	299A
fuel: Manufacture of —. (P) Rose	144A, 200A, 404A
mixtures: Apparatus for burning explosive —. (P) Lucke, and Gas and Oil Combustor Co.	293A
mixtures: Dilution limits of inflammability of —. Coward and others	435B
mixtures: Separating the constituents of —. (P) Ges. für Linde's Eismaschinen A.G.	507A
mixtures: Separating gases or vapours from —. (P) Beck	328A, 400A
mixtures: Separation of —. (P) Ges. für Linde's Eismaschinen A.G., and Pollitzer	328A
mixtures: Separation of constituents of —. (P) Lacy, and Roessler and Hasslacher Chemical Co.	570A
products of chemical reactions: Purifying and absorbing —. (P) Roy, and Morson and Son	359A
Gases: Absorption of light oils from —. Davis and Davis	645A
Apparatus for absorbing fixed quantities of — by liquids. (P) Braam	198A, 262A*
Apparatus for cleansing or washing — and extracting soot, dust, and other impurities therefrom. (P) Hindmarsh	45A
Apparatus for cooling or otherwise treating — with liquids. (P) Mathys	141A, 644A*

-silicon alloys unattacked by acids. Matigaon	375A
-silicon alloys; Prevention of graphite precipitation in manufacture of — (P) Maschinenfabr. Esslingen	628A
Smelting and purifying — (P) Gehrant	307A
sponge; Production of — (P) Sinding-Larsen	184A
sponge; Treatment of — (P) Sinding-Larsen	247A
Standard apparatus for determination of sulphur in — by evolution method. Pulsifer	515A
Sterilisation of water and removal of manganese and — therefrom by electrolytic means. (P) Tiemann	440A, 440A
-tantalum alloys; Determination of tantalum in —, Travers	244A
Titanium chloride as reducing agent in determination of — by titration with permanganate in hydrochloric acid solution. Brandt	719A
titanium, and silicon; Production of an alloy of — (P) Petinot, and United States Alloys Corporation	308A
Treatment of — to prevent corrosion. (P) Allen	308A
Use of metallic silver as reducing agent in volumetric determination of —, Edger and Kemp	391A
Use of phenylhydrosulphylamine-ammonium in the separation of — from zirconium, titanium, manganese, and aluminium. Brown	41A
for use in static transformers and other electrical apparatus. (P) Berry	127A
works in Japan; New —	382A
works in Norway; New —	184A
works; Proposed erection of — in Spain	20A
wrought; Manufacture of — (P) Aston, and Byers Co.	212A
wrought; Unusual features in the micro-structure of —, Rawdon	91A
-zirconium alloy. (P) Grenagle	95A

Iron disulphide; Formation of — by a wet method.

Rott	732A
hydroxide; Influence of — on catalytic activity of palladium hydrosol. Paal and Hartmann	579A
nitride. Maxted	107A
oxide; Action of — on silica. Le Chatelier and Bogitch	372A
oxide; Manufacture of catalysts from natural ores containing hydrated — (P) Fritzweiler and others	506A
oxide; Relation between molecular structure of — and its activity towards hydrogen sulphide. Weyman	333A
oxides; Malaga red — for paints	417A
oxides; Reduction of — (P) Gröndal	740A
phosphide; Manufacture of — from iron phosphatic material. (P) Webster, and Gray, jun.	425A
pigments; Manufacture of — (P) Hoffman	130A
salts as antidote to cottonseed meal injury. Withers and Carruth	105A

Iron—cont.	
salts and sulphuric acid; Production of a pigment from water containing —, (P) Parkin ...	136A
salts; Tanning with —, (F) Röhm ...	14A

precipitated as oxalate; Oxidimetric determination of —. Gooch and Kohayashi	225A	oxide; Preparation of very finely divided — from stannate liquors. (P) Krause	334A, 334A
Ratio of mesothorium to —. McCoy and Henderson	732A	oxychloride; A new —. Keller	29A
Recovery of — from monazite sand as pyrophosphate. (P) Welsbach Co. and Goltz	88A	Tints; Production of fast —. (P) Soc. of Chem. Ind. in Basle	6A*
Thorium nitrate market. Johnstone	375B	Titanic acid pigments resistant to chemical and physical agencies; Preparation of —. (P) Norske Aktieselskab for Elektrokem. Ind.	383A
Threads; Apparatus for treating artificial silk and like —. (P) De Chardonnet	6A*	Production of —. (P) Norske Aktieselskab for Elektrokem. Ind., Norsk Ind.-lyptekbank	301A
artificial; Manufacture of stable cuprammonium cellulose solution for production of — by use of sugars. (P) Glanzfaden A.-G.	575A	iron ores; Concentration of —. (P) Raffin et Fils	212A, 213A*
of cellulosic material; Method of treating —. (P) Vanderkleed and others	687A	oxide concentrate; Method for obtaining —. (P) Rossi, and Titanium Alloy Manufacturing Co.	581A
Manufacture of — from strips of paper, textile, or similar material. (P) Soc. Alsacienne de Constructions Mécaniques	461A*	Titanium; Determination of tungsten and vanadium in presence of —. Fenner	609A
Manufacture of — from viscose. (P) Verhave	764A	Influence of — on formation of pearlite in carbon steel. Vogel	421A
Use of liquid in motion for drawing off — in spinning viscous liquids. (P) Bernberg A.-G.	367A	iron, and silicon; Production of an alloy of —. (P) Petinot, and United States Alloys Corporation	308A
Thymol from ajowan seed	604A	Rossi's work on —.	73r
Thymolsulphophthalein; Use of — as indicator in acidimetric titrations. Clark and Lubs	718A	Use of phenylnitrosodihydroxylamine-ammonium in the separation of — from zirconium, iron, manganese, and aluminium. Brown	41A
Thyroid gland; Active principle of the —. Barger	33r	Titanium chloride as reducing agent in determination of iron by titration with permanganate in hydrochloric acid solution. Braundt	719A
Tiensa; Soda manufacture in —.	443A	compounds. (P) Spence and others	182A*
Tiles; Effect of pressure on subsequent contraction, tensile strength, and crazing of —. Watkin	208A	compounds; Manufacture of pigments from —. (P) Norske Aktieselskab for Elektrokem. Ind.	250A
Effect of variation of pressure in forming dust-pressed —. Pence	508A	dioxide pigments; Manufacture of white or light coloured —. (P) Norske Aktieselskab for Elektrokem. Ind., Norsk Ind.-lyptekbank	520A
Effect of variation in pressure and moisture upon the forming of dust-pressed —. Walker, jun., and Kerr	508A	dioxide; Use of — as filler for rubber products. (P) Barton and Gardner	14A
Kilns for —. (P) Bennett	513A	oxide paint and pigment; Manufacture of —. (P) Barton, and Titanium Alloy Manufacturing Co.	131A*
Ovens or kilns for use in manufacture of —. (P) Marlow, and Minton, Hollins, and Co.	243A	salts; Dyeing or staining and mordanting of leather with —. (P) Wrigley and others	477A
Timber; Kilns and chambers for drying —. (P) Halkes	515A*	<i>Tithymalus peplus</i> ; Rubber substitute from —.	397B
preservatives; Fluorides as —.	397A	T.N.T. See Trinitrotoluene.	
Preserving and drying —. (P) McMullen and McMullen	701A	Tobacco ash; Factors affecting composition of —. Roberts	173n, 446A
See also Lumber and Wood.		Effect of some alkaline salts upon the fire-holding capacity of —. Krynbyll	38A
Tin alloys; Use of hydrofluoric acid in analysis of —. Furman	445A	Preventing development of black rot and other fungoid and bacterial diseases in leaf —. (P) Garner and Beinhart	529A
-antimony-lead alloys. Ellis	112n, 246A	Process for extracting potash and other values from —. (P) Kennedy and others	149A
Apparatus for recovering — from waste material. (P) Considère and Bethell	96A*	Process for treating —. (P) Albertsen	749A
Apparatus for smelting —. (P) Morrill, and Andes Exploration and Smelting Corporation	552A	waste; Process for producing ammonia and potassium-containing material from —. (P) Zilk, and Odorless Fertilizer Manufacturing Co.	56A
-coated plates or sheets; Apparatus for manufacture of —. (P) Gilbertson and Co., and others	96A*	Tobacco; Cacao in —.	122n
conservation in United States	361n	Tariff alterations	121B
Crystal structure of —. Byl and Kolkmeier	658A	Tolane chlorides from calcium carbide, chlorine, and benzene. Davidson	202A
Determination of — in high-grade wolfram ores. Powell	241A, 285r	Tolu balsam; Evaluation of —. Cocking and Kettle	486A
assay; Use of lead as reducing agent in Pearce's —. Powell	241n, 285r	Toluene, benzene, and xylenes; Commercial fractional separation of —. Butler and Popham	220r, 455A
Determination of — in wolfram ores and concentrates. Smoot	471A	Determination of — in crude petroleum. Bowrey	
Effect of — on copper melts containing gases. Stahl	375A	Manufacture of side-chain chlorine derivatives of —. (P) Gibbs and Geiger	52A
Electrolytic refining of —. Kern	424A	Method of obtaining — from coal. (P) Pirani	363A
fumes; Removing — from smelter gases. (P) Hocking and Apor	426A	New source of —. Wheeler	201n
Government control of —	182r	Oxidation of —. (P) Selden Co., and Gibbs	684A
Imports of — into United States	397A	Process of chlorinating —. (P) Loomis, and Semet-Solvay Co.	763A
Influence of small quantities of — on mechanical properties of brass. Millington	149r	Production of — from turpentine. (P) McKee, and New Process Gasoline Co.	4A
-lead alloys. (P) Stockmeyer and Hanemann	740A	Rapid analysis of mixtures of chlorinated —. Luhs and Clark	684A
Ministry of Munitions order relating to —. 17r		Solidifying point of —. Formaeck and others	329A
ores; Buddles for concentrating —. (P) Richards	339A*	See also Toluol.	
ores; Concentration of —. (P) Webster and others	739A	Toluene-o and -p-sulphonamides; Freezing-point curve of mixtures of —. McKie	684A
ores; Effect of heating, and heating and quenching Cornish — before crushing. Yates	770A	Toluene-o and -p-sulphonic acids; Composition of mixtures of —. McKie	684A
ores; Elutriation of the crushed products of —. Truscott	376A	o-Toluidine; Separation of ethyl-o-toluidine from —. Price	83r
Oxidation of —. (P) Macnochie and De Ros	622A	Toluol; Manufacture of —. (P) Evans	118A*, 332A*
Oxidising or volatilising —. (P) Macnochie and De Ros	426A	New source of —.	153B
-plate; Manufacture of —. Bailey	92n, 113r	Production of — by cracking solvent naphtha in the presence of blue gas. Egloff	116A
(P) Godfrey and Way	591A*	production; Intensive —. Proposed improvements in the absorbing and stripping process. Lichtenhaeler	174A
-plate; Metallographic examination of —. Mayer	736A	production; Intensive —. Proposed improvements in the concentrating and refining process. Lichtenhaeler	263A
-plate; Volumetric determination of lead in —. Deininger	736A	Purification of commercial — from thiophen and similar compounds. (P) Dutt and Hamer	540A
-plates or sheets; Appliances used in manufacture of —. (P) Davies and Jones	428A*	recovery and standards for gas quality. McBride	174A
(P) Thomas and Davies	740A*	from spruce turpentine. Wheeler	364A
Plating ferrous metals with —. (P) Watkins, and Metals Plating Co.	213A*	See also Toluene.

smelting; Fine grinding and porous-briquetting of the charge in —. Johnson	270A
spraying process; Electrical —. Kasperowicz	548A
Utilising residues obtained in distillation of —. (P) Kohler and Baltin	629A
vapour; Condensers for —. (P) Norsk Elektrisk Metalindustri Aktieselskap	154A
vapour; Condensing —. (P) Fulton, and Metallurgical Laboratories, Inc.	590A
Velocity of dissolution of alloys of — with arsenic, lead, cadmium, nickel, platinum, and gold in acids. Centnerswer	246A
Volumetric estimation of —. Howden	719A
See also Spelter.	
Zinc chloride; Manufacture of —. (P) Cameron and others	415A
chloride; Manufacture of a difficultly soluble complex compound from dimethylamine, benzyl chloride, and —. (P) Chemical Works Rohrer & Co.	202A
compound for treating boiler feed water. (P) Paige, and Paige and Jones Chemical Co.	321A
ferrite; Formation of — in roasting zinc ores. Hamilton and others	210A
hydroxide; Influence of — on catalytic activity of palladium hydrosol. Paal and Hartmann	579A
oxide; Baghouses for —. Cregau	547A
oxide furnaces. Cregau	11A
oxide; Influence of impure — on determination of manganese. Muller	446A
oxide; Manufacture of —. (P) Macconochie and De Ros	622A
oxide; Manufacture of technical hydrated — free from chlorides. (P) Bayerische A.-G. für chem. u. landw.-chem. Fabr., and others	467A
sulphate liquors; Electrolysis and treatment of —. (P) Hunt and others	248A*
sulphate solutions containing arsenic and antimony; Purification of —. (P) Caples and others	371A
sulphide; Preparation of anhydrous —. (P) Comment	273A, 313A
sulphide; Use of — in white and luminous enamels. Schaefer	584A
white paint; Discoloration of —. Twiss	179A
Zinciferous ores; Treatment of —. (P) Gillies and Gillies	94A, 310A*
Zingiberone. See Methyl 3-methoxy-4-hydroxyphenyl-ethyl ketone.	
Zircon; Use of phenylnitrosohydroxylamine-ammonium in the analysis of —. Brown	41A
Zirconia bricks; Effect of load on refractoriness of —. Meller and Emery	371A
Manufacture of highly refractory ware from —. Arnold	734A
Manufacture of a new compound of zirconium and its application in the production of pure —. (P) Imperial Trust for Encouragement of Scientific and Industrial Research, and others	181A
Occurrence and application of —. Meyer	393A, 698A
as a refractory: Coley	254A
Rodd	213A
Zirconium; Colour reaction of — with pyrogallol-aldehyde. Kaserer	352A
Determination of — in ferrozirconium and steel. Ferguson	586A
-iron alloy. (P) Greengale	95A
ores; Process of purifying —. (P) Loveman, and National Carbon Co.	339A
Use of phenylnitrosohydroxylamine-ammonium in separation of — from titanium, iron, manganese, and aluminium. Brown	41A
Zirconium compounds; Use of — as rubber fillers. (P) Gardner	65A
sulphate; Production of a new basic — and its application in the production of pure zirconia. (P) Imperial Trust for Encouragement of Scientific and Industrial Research, and others	181A
sulphate; Silk weighting with —. Ristenpart	687A
Zuur pruim. See "Sea plum."	
Zymase; Kinetics of cell-free fermentation by —. Meyerhof	711A
Zymophosphate; Production of — by living yeast. Euler	386A

Imperial Institute; Bulletin of the:		Reagents and reactions. Tognoli (translated by Mitchell)	143n
Vol. XV., No. 4	236n	Refractive indices; Tables of —, Vol. I. Essential oils. Kanthack (Ed., Goldsmith)	466n
Vol. XVI., No. 1	330n	Resins; Distillation of —. Schweizer (revised by Stocks)	24n
Vol. XVI., No. 2	445n	Rothamstead experiments; The book of —. Hall and Russell	44n, 104n*
Indian arts and industries; The Madras exhibition of —, 1917	256n	Rubber; Crude —, and compounding ingredients. Pearson	352n
Indian Munitions Board handbook. Exhibition of food-stuffs and household requisites, 1917	256n	Rubber: its production, chemistry, and synthesis. Dubose and Luttringer	236n, 350n*
Indicators; Theory and use of —. Pridenax ...	64n, 331n*	Salt, bromine, and calcium chloride in 1917. Stone ...	424n
Industrial chemistry; Elements of —. Rogers ...	143n	Sands for furnace and foundry purposes; Memoir on British resources of refractory —. Boswell and others	404n
Industry, science, and education. Griffiths ...	64n	Sandstones; Tests of some Canadian — to determine their suitability as pulpstones. Cole	271n
Industry; What — owes to chemical science. Pilcher and Butler-Jones	143n, 236n*	Silica in 1917. Katz	424n
Ingot and ingot moulds. Breenley and Breenley	330n, 424n*	Silver, copper, lead, and zinc in the Central States in 1917. Dunlop and Butler	466n
Inorganic chemistry; Textbook of —. Caven ...	236n	Slate in 1917. Loughlin	388n
Inorganic chemistry; Textbook of —. Holleman and Cooper	44n, 164n*	Starch and cellulose; Modern chemistry and chemical industry of — (with reference to India). Chaudhuri	466n
Iron and Steel Institute. Carnegie Scholarship memoirs. Vol. IX.	445n	Steel structures. Quarterly Journal of Steel Structural Section of British Engineers' Association ...	466n
Kentucky Agricultural Experiment Station of the State University:		Strontium in 1917. Hill	330n
Twenty-sixth Annual Report, 1913	352n	Sulphate of ammonia; Manufacture of —. Calvert	188n, 212n*
Twenty-seventh Annual Report, 1914	352n	Sulphur, pyrites, and sulphuric acid in 1917. Smith	352n
Leiothion and allied substances. The lipins. Maclean	211n*	Synthetic drugs; Chemistry of —. May	352n, 481n*
Linseed oil; Chemistry of —. Friend	143n	Talc and soapstone in 1917. Diller	352n
Lubricants; American —. Lockhart	188n, 387n*	Tar distillation; Coal —. Warnes	143n, 144n*
Lubricants; Memorandum on cutting lubricants and cooling liquids, and on skin diseases produced by —.	404n	Temperature; Methods of measuring —. Griffiths	256n, 445n*
Magnetite in 1917. Yale and Stone	388n	Thiogen process of recovering sulphur from sulphur dioxide in smelter gases; The wet —. Wells	352n
Manganese and manganiferous ores in 1916. Hewett	388n	Tin in 1917. Knopf	466n
Metals; Chemical combination among —. Gioia and Gioia-Lollini (translated by Robinson) ...	271n, 403n*	Trade-unionism; An introduction to —. Cole	466n
Mica in 1917. Schaller	388n	United States. Annual chemical directory, 1918. Lovelace and Thomas	388n
Mine gases; Chart of properties of —. Burrell	466n	United States. Census of dyes and coal-tar chemicals	404n
Miners; Advanced first-aid instruction for —. A report on standardisation. Halberstadt and others	352n	United States dispensatory. Remington and Wood	256n, 386n*
Mines and mining; Abstracts of current decisions on — in the United States, Jan. to April, 1917. Thompson	352n	United States National Museum:	
Mines; Organising and conducting safety works in —. Wilson and Fleming	388n	Annual report for 1916. Rathbun	143n
Mining statistics; Report of committee on standardisation of — in the United States. Fay ...	352n	Annual report for 1917. Rathbun and Walcott	466n
New Zealand brown coals, with special reference to their use in gas producers and for low-temperature distillation. Rands and Gilling ...	445n	United States. Preparedness census of mining engineers, metallurgists, and chemists. Fay ...	352n
New Zealand. Mines statements. Macdonald ...	64n	Vapours; Recovery of — from gases, particularly of benzene and toluene from coal gas. Davis and Davis	445n
Oil analysis. Gill	312n	Wages; Payment of —. A study in payment by results under the wage system. Cole	466n
Oil fuel; Efficiency in the use of —. Handbook for boiler-plant and locomotive engineers. Wadsworth	466n	War; From — to work. Turner	312n
Oils and fats; Edible —. Mitchell	188n, 291n*	Waste products; Utilisation of —. Koller (revised by Stocks)	352n
Oils, fats and waxes; Technical handbook of —. Fryer and Weston	23n*, 24n	Water Board committee of Conjoint Board of Scientific Societies; Preliminary report of —	330n
Organic chemistry for advanced students. Cohen	370n	Welding; Autogenous —. Graojo and Rosenberg (translated by Richardsoo)	24n, 24n*
Paper; Recovery and re-manufacture of waste —. Strachan	290n, 403n*	Welfare; Standardising —. Leverhulme	330n
Peat fuel; Value of — for the generation of steam. Blizard	271n	Works manager of to-day; The —. Webb	371n
Petroleum and allied substances; Bibliography of —, 1915. Burroughs	352n	Zinc industry; The —. Smith	290n*
Petroleum refining. Campbell	370n	Zinc ores	123n, 188n*
Pharmacy; Practice of —. Remington	256n, 386n*		
Physiology; Directions for a practical course in —. Cramer	256n		

List of Patents Abstracted.

List of Journals Abstracted, with Abbreviations Used, and Addresses of Publishers and Prices.

JOURNAL.	ABBREVIATION.	ADDRESS OF PUBLISHER AND PRICE.*
Agricultural Bulletin of the Federated Malay States	Agric. Bull. F.M.S. ...	Dept. of Agriculture, Kuala Lumpur, F.M.S. 1s. 3d.
Agricultural Journal of India	Agric. J. India ...	W. Thacker and Co., 2, Creed Lane, London. 3s.
Agricultural Ledger ...	Agric. Ledger... ...	Reporter on Economic Products to the Government of India, Calcutta.
Agricultural Research Institute, Pusa, Report and Bulletins	Rep. (Bull.) Agric. Res. Inst., Pusa.	Supt. Govt. Printing, Calcutta. Price varies.
Allgemeine Zeitschrift für Bierbrauerei und Malzfabrikation	Allgem. Z. Bierbrau. u. Malzfabr.	Michaelerstrasse 25, Vienna XVIII/1. Krone 12 per annum.
American Journal of Pharmacy.	Amer. J. Pharm. ...	145, North Tenth Street, Philadelphia, Pa., U.S.A. 30 cents.
American Journal of Science	Amer. J. Sci. ...	New Haven, Conn., U.S.A. 50 cents.
Anales de la Sociedad Española de Física y Química	Anal. Soc. Espan. Fis. Quim.	Calle de Núñez de Balboa, núm. 21, Madrid. 15 pesetas per annum.
Anales de la Sociedad Química Argentina	Anal. Soc. Quim. Argentina	1790, Lavalle, Buenos Aires. 60 c.
Analyst	Analyst	Simpkin, Marshall, Hamilton, Kent, and Co., Ltd., 2, 4, 6, 8, Orange Street, London, S.W. 2s. (3s. from Jan., 1919.)
Annalen der Chemie ...	Annalen	C. F. Winter'sche Verlagshandlung, Leipzig, Germany. M. 28 per annum.
Annales de Chimie	Ann. Chim.	Imprimerie Gauthier-Villars et Cie., Quai des Grands-Augustins, 55, Paris. 28 fr. per annum.
Annales de Chimie Analytique	Ann. Chim. Analyt. ...	M. Crinon, 20, Boulevard Richard-Lenoir, Paris, 1 fr. 50.
Annales des Falsifications...	Ann. Falsif.	56, Rue Madame, Paris, 6c. 3 fr.
Annali di Chimica Applicata	Annali Chim. Appl. ...	Via Panisperna N, 896, Rome. Lire 34 per annum.
Annali della R. Stazione Chimico Agraria Sperimentale di Roma	Ann. R. Staz. Chim. Agrar. Sperm. Roma	R. Stazione Chimico-Agraria Sperimentale di Roma, Rome.
Apotheker-Zeitung	Apoth.-Zeit.	Levetzowstrasse 16b, Berlin, N.W. 87. 25 Pf.
Archiv der Pharmazie ...	Arch. Pharm.	Selbstverlag des Deutschen Apotheker-Vereins, Berlin, Germany. M. 12 per annum.
Atti della Reale Accademia dei Lincei, Roma	Atti R. Accad. dei Lincei, Roma	Tipografia della R. Accademia dei Lincei, Rome. Lire 10 per annum.
Australasian Pharmaceutical Notes and News	Austr. Pharm. Notes and News	Elliott Bros., Ltd., O'Connell St., Sydney, N.S.W. 3d.
Berichte der Deutschen Chemischen Gesellschaft	Ber.	R. Friedländer und Sohn, Karlstrasse 11, Berlin, N.W. 6, Germany. M. 32 per annum.
Berichte der Deutschen Pharmazeutischen Gesellschaft	Ber. deuts. Pharm. Ges.	Verlag von Gebr. Bornträger, Berlin, W. 35, Schöneberger Ufer 12a, Germany. M. 20 per annum.
Berichte des Ohara Instituts für landwirtschaftliche Forschungen	Ber. Ohara Inst. landw. Forsch.	Verlag der Ohara Seihōnōkai Kuraschiki Provinz Okayama. 1 yen.
Biedermann's Zentralblatt für Agrikultur Chemie	Biedermann's Zentr. ...	O. Leiner, Königstrasse 26b, Leipzig, Germany. M. 25 per annum.
Bio-chemical Journal ...	Bio-chem. J.	Cambridge University Press, Fetter Lane, London, E.C. 7s.
Biochemische Zeitschrift ...	Biochem. Zeits.	Verlag von J. Springer, Berlin, W. 9, Linkstrasse 23/24. M. 22 per volume.
Blast-Furnace and Steel Plant	Blast-Furnace and Steel Plant	Thaw Building, 108, Smithfield St., Pittsburgh, U.S.A. 15 cents.
Board of Trade Journal ...	Bd. of Trade J.	Messrs. Wyman and Sons, Fetter Lane, London, E.C. 3d.
Brewers' Journal	Brewers' J.	F. W. Lyon, Eastcheap Buildings, Eastcheap, London, E.C. 3. 3s.
British and Colonial Pharmacist	Brit. and Col. Pharm.	194-200, Bishopsgate, London, E.C. 1s.

* The price for single copies is given where these are sold separately. In other cases it is only possible to buy the Journals in question in complete volumes.

JOURNAL.	ABBREVIATION.	ADDRESS OF PUBLISHER AND PRICE.
Bulletin de l'Association Chimique du Sucre et de Distillerie	Bull. Assoc. Chim. Sucri.	156, Boulevard Magenta, Paris, 10c, France. 2 fr.
Bulletin of the Bureau of Agricultural Intelligence and of Plant Diseases	Bull. Agric. Intell. ...	International Institute of Agriculture, Rome. 2 fr.
Bulletin of the Forest Experiment Station, Meguro, Tokyo	Bull. Forest Exp. Stat., Meguro	Bureau of Forestry, Dept. of Agriculture and Commerce, Tokyo.
Bulletin of the Kentucky Agricultural Experiment Station	Bull. Kentucky Agric. Exp. Stat.	University of Kentucky, Lexington, Ky., U.S.A.
Bulletin of the School of Mines and Metallurgy, University of Missouri	Bull. School Mines and Met., Univ. Missouri	Director of Mining Experiment Station, Rolla, Mo., U.S.A.
Bulletin de la Société Chimique de Belgique	Bull. Soc. Chim. Belg.	M. J. Wauters, Palais du Midi (Galerie du Travail 7), Brussels.
Bulletin de la Société Chimique de France	Bull. Soc. Chim. ...	Masson et Cie., 120, Boulevard Saint-Germain, Paris, 6c. 38 fr. per annum.
Bulletin de la Société Française de Photographie	Bull. Soc. Franç. Phot.	51, Rue de Clichy, Paris, 9c. 1 fr. 50.
Bulletin de la Société Industrielle du Nord de la France	Bull. Soc. Ind. Nord ...	Rue de l'Hôpital Militaire 116, Lille, France.
Bulletin de la Société Industrielle de Mulhouse	Bull. Soc. Ind. Mulhouse	Berger-Levrault et Cie., 5, Rue des Beaux-Arts, Paris. 60 fr. per annum.
Bulletin de la Société d'Encouragement pour l'Industrie Nationale	Bull. Soc. d'Encour...	Secrétariat, Rue de Rennes 44, Paris, France. 36 fr. per annum.
Canadian Chemical Journal	Canad. Chem. J. ...	Biggar Press, Ltd., 540-541, Confederation Life Building, Toronto. 20 cents.
Le Caoutchouc et la Gutta-Percha	Caoutchouc et Gutta-Percha	A. D. Cillard fils, 49, Rue des Vinaigriers, Paris, X. 39 fr. per annum.
Chamber of Commerce Journal	Ch. of Comm. J. ...	Oxford Court, Cannon Street, London, E.C. 1s.
Chemical and Metallurgical Engineering	Chem. and Met. Eng.	McGraw-Hill Co., 10th Avenue at 36th Street, New York. 25 cents.
Chemical News	Chem. News	E. J. Davey, 16, Newcastle Street, Farringdon Street, London, E.C. 4d.
Chemical Trade Journal ...	Chem. Trade J. ...	Davis Bros., Danes Inn House, 265, Strand, London, W.C. 6d.
Chemiker-Zeitung	Chem.-Zeit.	Dr. v. Vietinghoff-Scheel, Cöthen, Auhalt, Germany. M. 9 per quarter.
Chemisch Weekblad ...	Chem. Weekblad ...	D. B. Centen, O.Z. Voorburgwal 115, Amsterdam. 10 fr. per annum.
Chemische Industrie ...	Chem. Ind. ...	Weidmann'sche Buchhandlung, Zimmerstrasse 94, Berlin, S.W., Germany. M. 20 per annum.
Chemische Umschau auf dem Gebiete der Fette, Öle, Wachse, und Harz	Chem. Umschau ...	Holland u. Josenhans, Lindenstrasse 13, Stuttgart. M. 1.75.
Chemische Zeitschrift ...	Chem. Zeitschr. ...	E. Buntrock, Berlin, S.W. 68.
Chemisches Zentralblatt ...	Chem. Zentr. ...	R. Friedländer und Sohn, Karlstrasse 11, Berlin, N.W. 6, Germany. M. 40 per vol.
Chemist and Druggist ...	Chem. and Drug. ...	42, Cannon Street, London, E.C. 6d.
Chimio et Industrie ...	Chim. et Ind. ...	49, Rue des Mathurins, Paris. 50 fr. per annum.
Collegium	Collegium	K. Schorlemmer, Sebastian-Münster-Strasse 28, Worms am Rhein, Germany. 2s.
Communications of the Netherlands Government Institute for advising the Rubber Trade and Rubber Industry	Comm. Netherlands Govt. Inst. for advising Rubber Trade	
Comptes-Rendus hebdomadaires des Séances de l'Académie des Sciences	Comptes rend. ...	Imprimerie Gauthier-Villars, Quai des Grands Augustins 55, Paris. 44 fr. per annum.
Comptes-Rendus des Travaux de Laboratoire de Carlsberg	Comptes-rend. Trav. Lab., Carlsberg	H. Hagerup, Copenhagen. Price varies.
Deutsche Zuckerindustrie ...	Deuts. Zuckerind. ...	Verlag der Gesellschaft, Die Deuts. Zuckerindustrie, Berlin. M. 24 per annum.
Elektrochemische Zeitschrift	Elektrochem. Zeits. ...	Viet u. Co., Marienstrasse 18, Leipzig. M. 1.50.
Engineering	Engineering	C. R. Johnson, 35 and 36, Bedford Street, Strand, London, W.C. 9d.
Engineering and Mining Journal	Eng. and Min. J. ...	McGraw-Hill Publishing Co., 10th Avenue at 36th Street, New York City. 20 cents.

JOURNAL.	ABBREVIATION.	ADDRESS OF PUBLISHER AND PRICE.
Färber-Zeitung	Färber-Zeit.	Julius Springer, Linkstrasse 23/24, Berlin, W. Germany. M. 4.60 per quarter.
Ferrum	Ferrum	W. Knapp, Mühlweg 19, Halle on Saale, Germany. M. 22 per annum.
Feuerungstechnik	Feuerungstechnik	O. Spamer, Täubchenweg 26, Leipzig-R., Germany. M. 5.30 per annum.
Gas Journal	Gas J.	W. King, 11, Bolt Court, Fleet Street, London, E.C. 8d.
Gazzetta Chimica Italiana ...	Gazz. Chim. Ital. ...	La Direzione della "Gazzetta Chimica," Via Panisperna, 89, Rome. Lire 4.
Gerber	Gerber	VI $\frac{1}{2}$ Gumpendorferstrasse 89, Wien, Austria. Kr. 17.50 per annum.
Gummi-Zeitung	Gummi-Zeit.	Geschäftsstelle der "Gummi-Zeitung," Blücherstrasse 31, Berlin, S. 61, Germany. M. 16 per annum.
Helvetica Chimica Acta ...	Helv. Chim. Acta ...	Georg & Co., 10, Freiestrasse, Basel. 25 fr. per annum.
Imperial Institute Bulletin	Bull. Imp. Inst. ...	John Murray, Albemarle Street, London, W. 2s. 6d.
India-Rubber Journal ...	India-rubber J. ...	Maclaren and Sons, 37 and 38, Shoe Lane, London, E.C. 3d.
International Sugar Journal	Int. Sugar J. ...	2, St. Dunstan's Hill, London, E.C. 1s. 4d.
Internationale Zeitschrift für Metallographie	Internat. Z. Metallog.	Gehr. Bornträger, Schöneberger Ufer 12a, Berlin, W. 35. M. 40 per annum.
Journal of Agricultural Research	J. Agric. Res. ...	U.S. Department of Agriculture, Washington, D.C., U.S.A. Price varies.
Journal of Agricultural Science	J. Agric. Sci. ...	University Press, Cambridge. 5s.
Journal of the American Ceramic Society	J. Amer. Ceram. Soc.	211, Church Street, Easton, Pa., U.S.A. 60 cents.
Journal of the American Chemical Society	J. Amer. Chem. Soc.	C. L. Parsons, Box 505, Washington, D.C., U.S.A. 60 cents.
Journal of the American Institute of Metals	J. Amer. Inst. Metals	10, Depot Street, Concord, N.H., U.S.A. \$3.
Journal of the American Leather Chemists' Association	J. Amer. Leather Chem. Assoc.	American Leather Chemists' Assoc., Ridgeway, Pa., U.S.A. 50 cents.
Journal of the Association of Official Agricultural Chemists	J. Assoc. Off. Agric. Ch m.	Williams and Wilkins Co., Baltimore, U.S.A., and Cambridge University Press, Fetter Lane, London, E.C. \$5 per annum.
Journal of Biological Chemistry	J. Biol. Chem. ...	2419-21, Greenmount Avenue, Baltimore, Md., U.S.A. \$3.25 per vol.
Journal of the Board of Agriculture	J. Bd. Agric. ...	Board of Agriculture and Fisheries, Whitehall Place, London, S.W. 4d.
Journal of the Chemical Society of London, Transactions	Chem. Soc. Trans ...	Gurney and Jackson, 33, Paternoster Row, London, E.C. 5s.
Journal of the Chemical, Metallurgical, and Mining Society of South Africa	J. Chem. Met. Soc., S. Africa	F. Rowland, Old Municipal Buildings, De Villiers Street, Johannesburg. 3s.
Journal de Chimie Physique	J. Chim. Phys. ...	Gauthier-Villars, 55, Quai des Grands Augustins, Paris. 25 fr. per annum; the price of a single copy varies according to the size.
Journal of the College of Agriculture, Tokyo Imperial University, Japan	J. Coll. Agric., Tokyo	Director of the College of Agriculture, Tokyo Imperial University, Japan. Price varies.
Journal of the College of Engineering, University of Tokyo	J. Coll. Eng., Tokyo	The University, Tokyo.
Journal of the College of Science, Imperial University of Tokyo	J. Coll. Science, Tokyo	Director of the College of Science, Tokyo Imperial University, Japan. Price varies.
Journal of the Franklin Institute	J. Franklin Inst. ...	The Actuary, The Franklin Institute, Philadelphia, Pa., U.S.A. 50 cents.
Journal für Gasbeleuchtung und Wasserversorgung	J. Gasbeleucht. ...	R. Oldenbourg, Glückstrasse 8, München, Germany. M. 24 per annum.
Journal of Industrial and Engineering Chemistry	J. Ind. Eng. Chem. ...	C. L. Parsons, Box 505, Washington, D.C., U.S.A. 60 cents.
Journal of the Institute of Brewing	J. Inst. Brewing ...	Harrison and Sons, 45, Pall Mall, London, W. 4s.
Journal of the Institution of Mechanical Engineers	J. Inst. Mech. Eng. ...	Storey's Gate, Westminster, S.W.
Journal of the Institution of Petroleum Technologists	J. Inst. Petroleum Tech.	The Institution, 17, Gracechurch Street, London, E.C. 5s.
Journal für Landwirtschaft	J. Landwirts. ...	P. Parey, Hedemannstrasse 10 u. 11, Berlin, S.W. 11. M. 12 per vol.

List of Errata, 1918.

No. of Journal.	Page.	Column	Line from top.	Line from bottom.	Corrigenda.
No. 1—Jan. 15	6R	1	—	30	For "R. M. Henderson" read "N. M. Henderson."
No. 2—Jan. 31	13A	2	—	4	For "Lnamnitz" read "Lomanitz."
	33R	2	—	11	For "Cements" read "Mortars."
	40A	1	—	14	For "Devel" read "Deval."
No. 3—Feb. 15	46A	1	—	25	For "R. H. Taylor" read "L. H. Taylor."
	46A	1	—	26	For "Blair" read "Bair."
	47A	1	—	19	For "Central" read "General."
	61A	1	31	—	For "Zinc" read "Tin."
No. 4—Feb. 28	100A	1	16	—	For "Isuga" read "Tsuga."
No. 5—Mar. 15	62R	1	28	—	For "10,300,888" read "2,509,456."
	62R	1	29	—	For "2,509,456" read "10,300,888."
	75T	2	—	3	For "Phosphorus" read "Phosphorus."
	127A	2	—	17	For "112,065" read "112,085."
No. 6—Mar. 30	156A	2	—	31	For "Vom Bauer" read "Vom Baur."
No. 8—Apr. 30	122T	2	—	1-2	For "crude protein" read "protein and fat."
	123T	1	10-11	—	The figures "18 or 19%" refer to the oil content of average American Upland seed, and the figures "30 to 35%" to the percentage of oil in the meats.
	206A	1	—	7	For "Wnnam" read "Wenman."
	208A	2	—	9	For "Assirate" read "Assirati."
	212A	1	—	4	For "Ashton" read "Aston."
No. 9—May 15	251A	2	15	—	For "1,275,698" read "1,257,698."
No. 11—June 15	222R	1	—	—	For "central" read "competent."
	291A	1	19	—	For "1,206,407" read "1,260,407."
	308A	2	—	9	For "Davies" read "Davis."
	312A	2	14	—	For "C ₃₀ H ₅₀ O ₂ " read "C ₃₀ H ₅₄ O ₂ ."
	313A	1	—	5	For "P. Akashi" read "K. Akashi."
	322A	1	32	—	For "E. H. Newcomb" read "E. L. Newcomb."
No. 13—July 15	198T	1	27	—	For "nitric acid and capric chloride" read "cupric chloride and nitric acid."
	198T	1	30-31	—	For "picric acid and capric chloride" read "cupric chloride and picric acid."
	198T	1	41	—	For "fig. 18" read "fig. 17."
	201T	1	—	6	For "72 tons and 26 tons" read "26 and 72 ft.-lb. respectively."
	380A	1	19	—	After "A.-G." insert "vorm. L. Schwartzkopf."
	389A	2	27	—	For "305,328" read "305,228."
No. 14—July 31	285R	1	8	—	For "barrel" read "ton."
No. 15—Aug. 15	308R	1	—	31	Insert "not" before "below."
	452A	1	12	—	After "Gregory" insert "Morrison."
No. 16—Aug. 31	274T	1	2	—	For "Earle" read "Earl."
	467A	1	—	19	For "Kahn" read "Kain."
	467A	2	—	8	For "J. Litinsky" read "G. Litinsky."
	467A	2	—	23	For "1,178,448" read "1,128,448."
	473A	1	16	—	After "compounds" insert "(A)."
	473A	1	17	—	After "Tenn." insert "(B) and (C) H. A. Webster, Columbia, Tenn. Assignor to J. J. Gray, jun."
	473A	1	18	—	For "1,265,460" read "1,265,150"
	473A	2	26	—	For "Lorimer" read "Larimer."
No. 17—Sept. 16	508A	1	20	—	For "H. J. Schurecht" read "H. G. Schurecht."
	527A	2	—	10	For "di-" read "digestibility of."
No. 18—Sept. 30	537A	1	4	—	For "Duoda" read "Duodo."
	547A	1	4	—	For "Davidson" read "Davison."
	555A	2	—	36	For "Tilston" read "Tilston."
	558A	1	—	25	Insert "3Y" before "hydrochloric," and for "0.1 grm." read "0.5 grm."
	560A	2	28	—	For "Panwitz" read "Pannwitz."
No. 19—Oct. 15	599A	2	—	39	For "litre" read "hectolitre."
No. 20—Oct. 31	618A	1	22	—	For "3/6,283" read "306,283."
	621A	1	—	12	For "R. Glaser" read "K. Glaser."
No. 21—Nov. 15	662A	2	—	33	For "J. B. Walker" read "T. B. Walker."
	667A	2	—	6	This line should read "constituents of milk caused by bacteria before any."
	673A	1	—	4, 8, and 16	For "myrtle" read "whortle."
	673A	1	—	13	For "The berries of the myrtle" read "Whortleberries."
No. 22—Nov. 30	430R	2	—	39	For "incineration" read "decolorising with charcoal."
	684A	2	—	8	For "Seldon" read "Selden."
	703A	2	12	—	For "Bateson" read "Batson."
No. 23—Dec. 15	739A	2	—	12	For "W. H. Kilbourn" read "W. D. Kilbourn."
	739A	2	—	23	For "Gooch" read "Groch."
	743A	2	3	—	For "305,898" read "305,808."
No. 24—Dec. 31	474R	2	37	—	For "Institute" read "National Union of Scientific Workers."
	761A	1	26	—	For "V. L. Reed" read "V. Z. Reed."
	769A	2	32	—	After "solution" insert "e."

INCOME AND EXPENDITURE ACCOUNT FOR YEAR ENDING 31st DECEMBER, 1917.

To the Members of the Society of Chemical In

We have audited the above Balance Sheet, dated 31st December, 1917, and have verified the investments.
 In our opinion the Balance Sheet shows correctly the position of
 the Society at 31st December, 1917.

TRANSACTIONS

Glasgow Section.

Meeting held at Glasgow, on Friday, October 19th, 1917.

MR. JAMES MACLEOD IN THE CHAIR.

RECOVERY OF POTASH FROM BLAST FURNACE DUST.

BY PROF. R. A. BERRY, F.I.C., AND D. N. MCARTHUR, B.Sc.

That the dust deposited from blast furnaces and kiln gases contained potash salts¹ is by no means a new discovery. In 1884 a patent was taken out by Hugh Barclay and Robert Simpson of the Harrington Iron Works, Cumberland, for the recovery of salts, especially potash salts, from coke-fed furnaces. Reference to similar patents occur in American literature.² At the Riverside Portland Cement Company's Works in California, a Cottrell electrical precipitation plant³ was installed in 1911 for the purpose of precipitating the dust from the kiln gases and the dust was found to contain potassium salts, the raw material containing 0.2% K_2O . Owing to the low price of potash salts at that time, the dust was not considered to be of any value but it was allowed to accumulate. With the outbreak of war, however, the whole position changed and this accumulated dust then became a product of considerable value. In 1915 the same company, every twenty-four hours, was recovering, from five kilns, from 20 to 25 tons of dust containing 5 to 20% of water-soluble potash (K_2O). De Beers⁴ calculated that 80,000 tons of potash could be obtained annually from such sources in the United States. Wysor⁵ found that the yellowish dust, which accumulates at the bottom of the stone chequer work in the stoves and gas fired boilers, contained 15% of water soluble potash (K_2O). Since the war started, he has gone into the question of the potash content of the raw material and of its recovery from the furnace gases and has drawn up a balance-sheet to show the weight of potash charged into the furnace and the amount recovered and lost. He estimates the greatest loss to be in the primary and secondary washers, amounting to some 56% of the whole, while in the slag some 20% is lost. The amount recovered in the dust from the stoves and boilers is under 1% of the potash charged. In 1916 an experimental Cottrell plant was installed, being connected to the gas main leaving one of the dust catchers and he found that practically all the dust entering the plant could be successfully precipitated. This dust contained on an average about 10% of potash (K_2O) and the colour varied from a light to a dark grey. The quantity of potash charged was 22.4 lb. per ton of pig iron produced and

deducting the amount of potash in the slag and dust catcher, namely, 6 lb., about 15 lb. per ton of pig iron appear to be left in the gases, which were then recoverable by the Cottrell process.

According to Burchard's⁶ figures the potash content of the iron ores varies greatly, from 0.17% to 2.56% K_2O in some American ores, the average being 0.63%. Grasby⁷, however, gives the average as 1.32%, the lowest being 0.70% K_2O and the highest 2.29%.

The production of pig iron in the United States in 1916 amounted to over 39,000,000 tons⁸, so that if Wysor's figures are correct then the flue dust from the coke-fed furnaces in the States is a great addition to the potash supply.

In Scotland, however, the recovery of potash from blast-furnace gases is a rather different problem, as not only is the potash content of the iron ores used probably lower, but coal instead of coke is normally used. In the case of the coal-fed furnaces much tarry matter is produced. With the coke-fed furnaces, as in England, this is absent so that the gases are not washed but led from the dust catcher direct to the stoves and boilers, the dust being deposited in the dust catchers, tubes, stoves and at the base of the chimney stack.

Cranfield⁹ states that from one furnace per week 20 tons of a coarse black dust are deposited in the dust catcher, 5 tons of a reddish dust in the stoves and boilers, and 1 ton of a cream-coloured dust at the base of the chimney stacks. The potash (K_2O) content of each is 2.5%, 7.0%, and 10% respectively and a total annual yield from the furnaces in Great Britain of 15,000 tons of potash (K_2O) is estimated. His estimate is, however, too high as he assumes that the Scottish furnaces are producing dust at the same rate as the English ones. Coke fed furnaces are driven harder with a blast of about 12 lb. compared with 5 lb. in the Scottish practice and consequently more dust is produced in the English works.

As the amount of dust produced in the Scottish practice is relatively very small, the spent liquor, which according to Wysor is the main avenue of loss, seems more deserving of attention. So far as we are aware there are no published analyses of the spent liquors; while the analytical data showing the potash content of the raw materials are almost equally unsatisfactory. The potassium is present mostly in combination with silica and its amount will vary largely. Probably the silicates of potassium, at the high temperature reached at the base of the furnace, interact with other components of the charge liberating the potassium as oxide which, in turn, reacts with the sulphate and chlorides present to form potassium salts. Potassium cyanide is found at certain regions in the furnace, but is again decomposed, the nitrogen being given off as ammonia and free nitrogen, and the potassium probably as oxide or carbonate. The high temperature vaporises the potassium compounds and the

vapours, as they pass into the cooler parts of the furnace, condense in the form of fine dust particles which are carried over along with the dust from

potash (K_2O) was first determined in each sample and subsequently the total potash in several samples.

the fuel and ores. The heavier particles are deposited in the dust catcher and form a coarse black powder. Inside the main tube a thick coating of carbonaceous matter is formed which is periodically cleaned out and forms, along with the dust from the dust catcher, the "tube cleanings."

The furnace gases contain a large proportion of tarry matter, from the coal, which condenses and encrusts much of the mineral matter. Most of the heavy tarry matter separates in the condensers and in settling carries down with it a considerable quantity of the fine dust. The rest of the tarry matter, the ammonia, and most of the remaining fine dust are then caught by the water during the cleaning of the gas in the scrubbers. The gases on leaving the scrubbers should only contain a very little mineral matter and this is caught in the stove and boilers forming the stove and boiler dust. The spent liquor, from which the bulk of tarry matter and the ammonia have been extracted, is at present allowed to escape except at Messrs. Baird and Co.'s Lugar and Muirkirk plants and at the Dalmeilington Iron Co.'s Works, Dumaskin, where for several years the potassium salts have been recovered by evaporating the spent liquors. Samples of the spent liquors and of the dusts were received for analysis towards the end of May, 1917, from the different plants in Scotland and their potash content was determined with a view to forming an estimate of the quantity of potash which might possibly be recovered.

Consideration may be first given to the dusts:

Flue dust.—Nine samples were received. The dusts were of a very fine powdery nature but

The water soluble potash (K_2O) varied from 4.07% to 19.19%, the average being 8.86%. It was not possible to correlate colour and potash content.

A qualitative examination of the dust usually showed in addition to potassium, the presence of iron, aluminium, calcium, magnesium, sodium, and silica, while in many lead and zinc were also found. Chlorides, sulphates, and carbonates were the predominating acid radicles.

The highest yield of dust per annum at any one of the plants was 21 tons. The one plant using coke fuel gave a yield of 300 tons per annum—due to a greater blast, and to the absence of tarry matter, but the potash content was low, namely, 3.13%. Excluding the latter the total production per annum of flue dust in Scotland from the coke-fed furnaces does not reach 100 tons, and taking the present value of the potash at 15s. per unit, the estimated total value is £550, whilst the estimated value of dust from the coke-fed furnaces amounts to £700 per annum as against £150 and £190 respectively if valued at the pre-war rate of 4s. per unit of potash (K_2O).

Stove dust.—Only three samples were received. The potash content varied between 6% and 8% water-soluble K_2O . With the exception of the plant using coke fuel, the yields are negligible. In this case the yield was 150 tons per annum, the total potash content being 13.6% K_2O and the water-soluble potash 7.6%. These values are given in Table II.

The total potash was determined in five samples of dust and the percentage of the total potash soluble in water ranged from 40 to 89.

In this dust average % total potash (K₂O) water-soluble is 69.3.

only a very small percentage of water soluble potash, the highest being 2.7% and the lowest under 1%, only a few samples were analysed. The value of these dusts is however high in comparison with the other dusts on account of the great quantities of cleanings annually produced. According to estimates supplied, the total quantity of tube cleanings produced per annum from the Scottish furnaces amounts to nearly 15,000 tons.

in blast, the structural differences in individual plants, the efficiency of the washing and the potash content of the raw materials. Considerable variation must be expected in the raw materials according to the nature of the coal, the iron ore, and the limestone used. As stated above, published data showing the potassium content of the raw materials are not available.

The potassium salts could be extracted with

Total yearly value of ash from 4 coal-fed furnaces at 15s. per unit K₂O .. £3990 approx.
Total yearly value of ash from 4 coal-fed furnaces at 4s. per unit K₂O .. £1040 approx.

Spent liquor.—Fifteen works supplied samples. Two samples were taken from each plant at an interval of one week. The method of sampling consisted in taking a ladle-full—about $\frac{1}{2}$ gallon—every hour during the 24 hours and, from the composite sample, a further one gallon was drawn for analysis. The specific gravity, total solids, ash and water-soluble potash in the ash were determined in each sample.

Owing to the presence of the tarry matter evaporation was greatly retarded. The Cottrell process has been employed for precipitating coal tar products^{10, 11}. If the temperature was kept above the vaporising point of the light oils, etc., the heavy tarry matter might be precipitated out with all the dust and thus produce a partial cleansing of the gas. This pitch might then be burnt.

The potassium was present mainly as sulphate and chloride except in one or two cases where a fair percentage of carbonate was found.

The ash was usually white or grey. The duplicate analyses varied considerably in many cases but on the whole the agreement was considered satisfactory. The highest percentage of K₂O found was 55.7% from firm No. 6 and the lowest 20.6% from No. 8, the average being 33.5%. The potash content of the ash was high, but the yield of ash was disappointing. The highest yield estimated for any one plant was 318 tons at No. 12 and the lowest 17 tons at No. 8, while the total yield of ash was 1696 tons.

The factors which would account for the variation in yield comprise the number of furnaces

water or the ash, without further treatment, might be used as a manure. The value of the ash is given in Table V. No. 1 plant yields 257 tons containing 31.4% K₂O soluble in water and at the present market price of potash, namely, 15s. per unit, this quantity is valued at £6052 or at £1614 on the pre-war basis of 4s. per unit K₂O. No. 12 plant yields 318 tons containing 22.3% K₂O soluble in water and valued at 15s. per unit of potash represents £5286 or £1418 on a 4s. per unit basis. The total value of £1696 tons containing an average of 33.5% water-soluble potash (K₂O) is £44,312 on a 15s. per unit basis and £11,500 on a 4s. per unit basis. These data refer to 15 plants using coal fuel and having a total of 72 furnaces in blast. The question of the advisability of evaporating the spent liquor must be decided by each firm for itself. When the yield of ash reaches 100 tons and its value between £2,500 and £3,000 and when spare heat and exhaust steam are available, the matter is worthy of serious consideration. It is, however, necessary to remember that the prices per unit of K₂O in pre-war days was about 4s. and it may again fall to that figure after the war. The erection of evaporating plants at most of the works would be necessary and, at the present time, the cost of so doing would be high. Preliminary concentration of the liquors, where exhaust steam is available, is recommended and, owing to the scum of tarry matter which forms on the surface, this must be facilitated by mechanical stirring and splashing with furnaces of the Porion type or by other means. According to an

Average % water-soluble potash 33.5
 Total yearly yield of ash from 15 coal-fed furnaces 1696 tons
 Total yearly value of ash at 15s. per unit K₂O £44,575 approx.
 Total yearly value of ash at 4s. per unit K₂O £11,513 approx.

estimate supplied to us by Messrs. Gillespie and Son, Consulting Engineers, Glasgow, an evaporating plant of this kind to deal with 20,000 gallons daily, would cost £4000 and to deal with 100,000 gallons daily would cost £14,000. If spare heat is available then the capital outlay may be wiped off in a few years. Even if the value of the potash salts recovered is sufficient only to pay the running expenses of the plant, then evaporation of the spent liquor is perhaps the best way for its disposal.

Sources of loss.—Considering that such relatively small quantities of potash are recoverable in the dust and spent liquor, the question arises as to what is the weight of potassium charged into the furnaces and what are the sources of loss. The principal losses would be in the pitch and slag.

"Pitch" from blast furnaces contains much more mineral matter than that from coke and coal gas plants. According to the conditions of deposition and recovery of the tarry matter, the percentage of the amount of ash in the pitch will vary in different works. Figures which have been supplied to us, indicate that the ash content varies from 10% to 25%, the average being about 15%. Devices such as filtration, centrifuging and so forth are in use to remove the ash. It is also possible that the percentage of potash in the ash from any one plant may vary. An analysis of the pitch from No. 1 plant shows it to contain 17% of ash and the ash 8.8% of water-soluble potash. The yield of pitch per ton of coal burnt varies from 98 lb. to 140 lb. at different plants, the average being about 112 lb. The pitch left, after the recovery of the light oils, etc., from the tar, also varies at the different works, as, for example, at No. 1 plant it was 70% of the tar while Gray and Mellanby¹² put the figure at 65%.

When the ash content is 15% and 8% of this is water-soluble potash it would, with pitch at 12s. per ton, pay to burn the latter as fuel and collect the ash. On the basis of these figures and ignoring the insoluble potash 1 ton of ash could be obtained from 6.6 tons of pitch and, with the market price of potash at 15s. per unit (K₂O), would be worth £6 without taking into account the fuel value, while the initial cost of the pitch at 12s. per ton would be approximately £4. At the pre-war rate of 4s. per unit the ash would only be worth £1 12s. The burning of the pitch might produce difficulties but these doubtless could be overcome.

The coal consumed in blast furnaces in Scotland

in 1915 amounted to 1,478,924 tons, so that on an average production of 112 lb. pitch per ton of coal, then the total yield of pitch would be about 74,000 tons. If all the pitch were burned, 11,092 tons of ash containing 8% K₂O would be obtained and at present prices would be worth £41,596 and at pre-war prices £11,100.

"Slag." The quantity of slag produced per ton of pig iron varies according to the purity of the iron ore and limestone and the weight of slag also varies from 9 cwt. to 23 cwt. per ton of pig iron produced at the different plants. The slag contains potassium, 0.24% K₂O being found in slag from Firm No. 1, but at present it does not seem feasible to recover this.

Balance Sheet.—The amounts of potash in the raw materials—coal, coke, iron ore, and limestone, and in the slag and other by-products from No. 1 plant have been determined and are as follows: Spent coal 0.040% K₂O, coke 0.121%, iron ore 0.128%, limestone 0.136% K₂O. A balance-sheet was drawn up with the following result:—

Total potash charged into furnace—7.6 lb. per ton of pig iron.

Potash recovered—	
In spent liquor	1.4 lb. per ton of pig iron.
In line and stove dust	0.04 " " "
In pitch	1.7 " " "
In tube cleanings	0.2 " " "
In slag	2.7 " " "
Total	6.04 " " "
Unaccounted	1.6 " " "

The deficiency is due to other sources of loss in the furnace and in the running off of the slag, pig iron, etc.

The iron ore was the principal source of the potash, while the coal did not supply much more than the limestone. In contradistinction to these results Sir Lothian Bell states in his work on "Chemical Phenomena of Iron Smelting" that the potash is derived from the coal.¹³

The balance-sheet is in great contrast to that obtained by Wyss. Too much stress, however, cannot be laid on the fact, that our figures are only applicable to the raw materials and to the plant in question.

Although it has not been possible in the time at our disposal to obtain similar figures from other works, these figures may be extended, generally, to those plants using Welsh limestone and a mixture of Spanish ores. Thus taking the production of pig iron in Scotland for 1916 at 1,144,756 tons and the potash charged into the furnaces at 7.6 lb. per ton of pig iron, the total weight of

potassium would amount to 3884 tons, more than one half of which is recoverable.

In Scotland 12 companies having 17 works, a total of 102 blast furnaces, produce potash-bearing by-products.

The total quantity of potash recoverable from these by-products is as follows:—

	Tons K ₂ O.
Spent liquor 1694 tons containing 35.5% wat. sol. potash	567.4
Flue and stove dust about 100 tons do. 8% do.	8.9
Pitch ash about 11,092 tons do. 8% do.	885.8
Tube cleaning dust about 8,250 tons do. 2.5% do.	206.9
Total production	1667.2

The figure is, relatively, a very small one, but it represents water-soluble potash. It is hardly possible with the data we have to estimate approximately what the total amount of insoluble potash would be. The insoluble potash might be rendered soluble by a process similar to that of Rhodin¹⁴. The heat from burning the pitch and the tube cleanings could be utilised for evaporating the spent liquor.

As the total requirements of potash for the British Isles is estimated to be 32,000 tons per annum, there is good reason to believe that if the different sources of potassium in this country (see Bibliography) were developed to the fullest extent, the country's requirements in potash salts would be more than met.

In any scheme of development of this nature, after war conditions have passed away, it must always be borne in mind that if the Alsatian deposits come into the occupation of their rightful owners, as they must, there will be available an almost unlimited supply irrespective of the deposits in Germany.¹⁵

In conclusion we wish to thank the different companies for their very sympathetic co-operation in the work and in particular Mr. A. K. McCosh for his help and advice at every stage of the investigation.

MR. JAMES MACLEOD IN THE CHAIR.

THE DISTILLATION OF WOOD.

BY JAMES C. LAWRENCE, A.B., C.I.E.

The distillation or carbonisation of wood is a subject which is becoming increasingly prominent amongst the world's industrial activities. We have heard a great deal in the past three years about so-called "key industries," and their importance to the industrial and commercial development of the country. The wood distillation industry may, I think, be classed among the minor key industries, particularly in view of the ever-increasing range of uses of the prime and derived products.

The art in its elementary form dates back to the prehistoric ages, for we read of charcoal burners and their activities in the historical tales of every century. As to when and where the first commercial step forward from the mere carbonising of wood for the production of charcoal to the condensation of the gases was taken, who can say?

In Britain among the earliest factories was that of Messrs. Shirley Aldred and Co., established in 1796, long before the advent of railways. Their works was established near Rotherham for the production of charcoal to supply the metal trades at Sheffield, and to supply the chemical trades at Manchester with acetates and acetic acid. The chemicals were carted over the roads fifty miles to their destination. It is interesting to note that of some seven plants erected subsequently in that district there are only two remaining, of which the above is one, the lack of wood and the loss of the demand for charcoal due to discontinuing manufacture of charcoal iron being among the principal reasons for their abolition. There were also several works established in Scotland at an early date, some of which are still in operation, and operating to-day on lines very similar to those originally used. It is a remarkable fact, although not so remarkable when the fact that Scotsmen were the entrepreneurs is recalled, that from one of these Scottish works sprang the whole immense industry of wood distillation in the United States of America. About 1819 Messrs. Turnbull of Glasgow built and operated the first complete American wood distillation works at Millburn, N.Y. Messrs. Turnbull sent over their own equipment and workmen, and the works was consequently known, and is known to-day, as the "Scotch Works." The original workmen gradually dispersed into other new factories in the United States, so that from this one factory the industry grew very gradually to its present proportions.

Continental development may be said to be similar to British, but on a larger scale. The United States produces about 50% of the world's requirements, Canada and Europe an equal amount, of which about 80% is produced in the Central Empires. The amount of wood distilled throughout the world for by-products is approximately three million tons annually, or about two million cords of 128 cubic feet each.

The ramifications of the industry to-day are evident in an almost inconceivable number of activities. Manufacturing works of many kinds are using the immediate products or derived products from the distillation of wood. Originally, as has been noted, charcoal was the only substance obtained. This was followed at an early date by crude acetic acid and the various acetates. Later a demand for wood spirit or alcohol and tar grew up and these materials were consequently collected. At present the four prime products obtained at the majority of works are as follows:—

1. Charcoal.
2. Acetate of lime (grey).
3. Wood alcohol.
4. Tar.

More recently, owing to the increasing costs of raw material (wood), fuel, and labour, and to increasing competition and consequent lowering of prices, the larger works first, followed eventually by the smaller, were forced to methods of increasing income by increasing their efficiency and making use of what were formerly considered waste products. This gradually resulted in the saving and production of light oil, wood oils, first runnings from alcohol distillation known as methyl acetone or alcohol-acetone, sifted charcoal, fertiliser "filler," etc.

Following on this came the manufacture of derived products from the prime products, such as acetic acid, esters, and acetone from acetates, formaldehyde from methyl alcohol, pure drugs such as creosote, guaiacol, etc., from the tar, and from these products a whole series of organic chemicals, dyes, and drugs required in the arts and industries to-day. These latter developments

are being proceeded with owing largely to the very successful beginning made in combining the production of refined acetic acid with the crude plants. As by far the largest portion of the acetate made is used in normal times for producing acetic acid, naturally the greatest development came in this line. Acetic acid plants are in operation in connection with wood distillation plants producing continuously a redistilled pure glacial acetic acid and showing yields of from 91—95% of the theoretical.

In connection with the principal products of the industry used in this country it may be of interest to note the amounts imported and used here in the past few years (average per annum 1913, 1914, and 1915), calculated from figures given in Bull. Imp. Inst., Vol. 14, No. 4:—

Acetate of lime	4709 tons.
Acetic acid	4257 tons.
Acetone	3430 tons.
Wood alcohol	589,148 galls.
Wood tar	12,148 tons.

Of this about 20% is imported from Canada. The amount of acetate of lime imported is sufficient only for the production of half the acetic acid import, supposing none were used for other purposes, thus leaving an amount to be made up necessary to produce acetone and other products imported equal to over 20,000 tons.

To produce the wood alcohol imported would require from 60,000 to 80,000 cords of wood per annum, which would, in addition, produce roughly 8000 tons of acetate. The wood available in Great Britain under present conditions of forestry and lumbering would not support such an increase in the industry, but the remedy lies in Colonial development, as will be mentioned later.

In discussing the distillation of wood, it must be pointed out that the industry itself is broadly divided into two major divisions, both of which are subdivided into several minor subdivisions, each having its distinct type of plant and methods of operation. The major divisions are known as soft wood or coniferous wood distillation, and hardwood or deciduous tree distillation.

Softwood distillation deals with woods containing resinous substances and oils in addition to the cellulose substance, but only a very small proportion of ligno-cellulose bodies. Distillation of such wood produces products of an entirely different nature from those obtained in treating hardwood, which is primarily composed of cellulose and ligneous matter, and contains no resins or oils.

Softwoods, such as pine, fir, spruce, etc., produce large quantities of crude oils and tar, but very little acid and alcohol, whereas hardwoods, such as oak, birch, beech, maple, elm, etc., produce very small quantities of oils and tar, but large amounts of acid and alcohol.

The softwood plants are subdivided into the following types, which derive their names from the method of treatment:—

1. Destructive process, in which the wood is heated as in hardwood distillation, the oils being driven off, and the resins decomposed.

2. Solvent extraction process, in which the wood is treated with either a volatile solvent or molten resin which is recovered and re-used.

3. Alkali extraction, in which the wood is treated as for the manufacture of paper pulp, the volatile oils being recovered by condensation.

4. Steam distillation process, in which the wood is treated by live steam under pressure, the oils being condensed with the steam.

Hardwood distillation, on the other hand, is made up of much simpler subdivisions, the process being almost entirely one of destructive distillation, but carried out in the following types of plants:—

1. Retort plants, in which the wood is treated in small retorts holding from 1 to 5 tons.

2. Oven, or large retort plants, in which the wood is handled in trucks, each oven treating from 10—15 tons per charge.

3. Kiln plants, being of the beehive type, holding 50—75 cords at a time.

4. Mechanical plants, dealing with chippings and shavings only, and operating continuously.

The detailed description of the processes and types of plants used in the softwood industry must be omitted from this paper owing to the limits of time and space, only a few important facts and comparisons being admissible, since the principal activity and interest in this country is in hardwoods.

Referring, therefore, to the types of hardwood plants, we may consider, for purposes of description, the small and large retort plants as one type. These plants make use of cord wood, slabs and edgings, blocks or small wood, tops, branches, etc., ranging in thickness from 1 in. or less to 6 ins. and 8 ins., but preferably about 4 ins. diameter. They are the most usual type of installation where timber is grown or in connection with large saw-mills—in other words, where wood is fairly cheap and of uniform quality. They are installed where the industry is primarily one for the production of chemicals, and may vary in size from 5 to 150 tons of wood per day.

The kiln type of plant is gradually being eliminated, as the yields of products are only about half those obtained from retorts. Their greatest use has been in connection with the production of immense quantities of charcoal for use in iron smelting, the recovery of the by-products being a secondary consideration. They use cord wood, slabs, etc., and the distillation is effected by the partial combustion of some of the wood itself, so that in consequence, part of the gases is decomposed. They are an uneconomical and inefficient type and are very unwieldy in operation. Consequently they are rapidly being replaced by oven or large retort plants.

The mechanical retort plants which use chips and shavings are naturally few in number, due to the fact that they deal with only a very special class of wood, to the various mechanical difficulties encountered in the mechanical operation of moving parts at such high temperatures, and also due to the difficulty in controlling temperatures and obtaining suitable yields of certain of the products from wood in such finely-divided condition where a large surface is exposed to the heat.

Before proceeding to a detailed consideration of the hardwood distillation plants, it may be of interest to interpolate some data and comparisons in connection with softwood distillation by the distillation process.

The woods sufficiently rich in resin to permit of profitable distillation by the distillation process are pitch pine, or long leaf yellow pine, Norway pine and fir. Small retorts are usually used, sometimes with oil jackets, as it is very important that the temperature be under accurate control. The wood is loaded in cordwood sizes and heated gently. The temperature is kept below 200° C., until all the turpentine and low boiling oils are driven over and condensed so that no charring of the wood takes place. If the temperature be allowed to rise above this point the spirit is contaminated by decomposition products of resin, etc., from which it is extremely difficult to free it. After the light oils are removed the temperature is raised to the usual degree for carbonisation, and the acid liquor and heavy oils are collected in a separate receiver. The time required for these woods is from 24—30 hours.

The immediate crude products are charcoal residue, non-condensable gas, tar, oils, and acid liquor. The tar is either shipped as such—Stock-

holm tar of commerce—or may be redistilled by fire or superheated steam, yielding light oils, creosote oils, pitch, and acid water. The crude oils are fractionated with steam several times and yield:—

Rosin spirits distilling between	80° and 150° C.
Wood turpentine	150°—180° C.
Pine oils	175°—250° C.
Rosin oil	250°—400° C.

The acid liquor is neutralised with lime, distilled to remove wood spirit, and evaporated to dryness to produce acetate of lime.

The yields of products in softwood destructive distillation plants vary between extremely wide limits, due almost entirely to the "richness" or "leanness" in resin of the wood used. The species differ so greatly one from another in the amount of resin and oils contained that no definite statement can be made regarding yields from softwoods as can be done with a greater degree of accuracy in connection with hardwoods. The subjoined results of tests on two charges of four cords each illustrate the great differences observed. One charge was made with a very rich pitch pine wood, and the other with a lean batch of pitch pine. The products obtained from a 4-cord charge of hardwood are appended for comparison.

TABLE I.

Products.	4 cords rich wood, wt. 16,600 lb.	4 cords lean wood, wt. 16,000 lb.	4 cords hard wood, wt. 14,000 lb.
Charcoal	4284 lb.	4100 lb.	3600 lb.
Refined turpentine ..	41.5 galls.	20.75 galls.	—
Pine oil	11.6 "	4.2 "	—
Rosin spirit	21.5 "	12.0 "	—
Rosin oil	141.0 "	64.75 "	—
Creosote oil	46.5 "	21 "	20 galls.
Acetate of lime 80% ..	390 lb.	350 lb.	852 lb.
Wood alcohol (spirit) ..	6 galls.	9.6 galls.	37.5 galls.
Pitch	1400 lb.	625 lb.	720 lb.

The refining and separating of the crude oils calls for apparatus of a particular type, since these oils are composed of a heterogeneous mixture of rosin spirits, turpentine, pine oils, and rosin oils with boiling points respectively varying from 80° to 400° C.

Innumerable distillations in ordinary pot type stills are required to obtain any degree of separation, so that column stills of a high degree of rectifying efficiency are necessary. Fortunately the lighter oils such as rosin spirit and turpentine are easily distilled in live steam, while the pine oil and rosin oil are more difficult to carry over in this medium. Even with columnar stills having the usual single column, however, it requires several distillations and the redistillation of various fractions to obtain a perfect separation which would produce a pure refined turpentine free from the other products. Using single column stills, the first operation removes the rosin spirit, and then a small quantity of intermediate product containing some turps. This is added to the first crude oil distilled. The residue from the first run is re-run and a refined turps obtained, also a second intermediate product, which latter is re-run along with the following charge of second-run oils.

The residue from the second run is nearly all pine oil and rosin oil, which are then re-run alone and the pine oil collected, the residue being the rosin oil, which may be fire-distilled to remove carbonaceous matter.

It will be seen that the running of a pure turpentine and a pure pine oil was rather a tedious process, requiring careful operation and considerable quantities of fuel. Within recent years the demand for pine oils, rosin oils, creosote, etc., has greatly increased due to the sudden demand for these oils for mineral separation from ores by the

flotation process. It became necessary to deal with large quantities of oils, so that the single column method was considered too cumbersome and expensive.

Our present practice is to combine two, three, or four stills in one, and operate them continuously, fractionating the several products in successive portions of the same still. It was determined experimentally by Veitch and Donk (U.S. Dept. Agric. Bureau of Chem., Bulletin 144) that refined turpentine was being distilled when the proportion of oil in the mixture of oil and water condensed was 55%, and similarly pine oil was produced when the proportion of oil to water in distillate was less than 35%. Working from these figures a scheme of distillation and rectification was drawn up. Each column has a known number of plates and sufficient rectifying surface to produce the mixture of oil and water necessary for the particular product to be condensed. In this way the various intermediate products remain continually in the system, rising and falling over a few plates, but never reaching the outlet, as they are continually being enriched in one component through the introduction of fresh liquor, and alternately being impoverished by the withdrawal of another component to the higher rectifier.

While the mechanical process, as has been stated, is confined to a comparatively small proportion of the total wood used, it is interesting to compare and discuss the manner in which it differs from the cordwood or retort type of plant. It will be readily realised that the main difference lies in the retort itself. The products obtained are similar in kind to those obtained from cordwood retort plants, differing only in quantities, hence the refining equipment will be described in connection with the cordwood retort process.

The continuous or mechanical retorts now in operation are of two distinct types—the horizontal, which seems to be the most used, and the vertical. The horizontal mechanical retort which is most in use consists simply of an oblong metal box, divided horizontally across the middle by a plate; chain drums at each end, operated by gearing, serve to carry endless chains with a series of scrapers over the horizontal plate the entire length of the retort, returning along the bottom plate to the point of starting. The chips are fed into the retort at the same end as discharged, hence they travel twice the length before being completely carbonised and ready for removal. The rate of travel and supply of wood are regulated so that carbonisation is complete in the cycle. The gases are usually removed at the top of the retort through pipes of ample area and pass to condensers in the usual manner.

Another horizontal mechanical retort makes use of the spiral conveyor, the chips, etc., being fed in at one end and charcoal discharged at the other.

Another type in successful operation is composed of a large chamber over the floor of which travels an endless chain guided by rollers and carrying vertical scrapers. The chain passes back and forward across the floor of the chambers several times, turning the chips with the scrapers until the carbonisation is complete.

The only successful vertical mechanical retort within the author's knowledge is Ross and Corner's patent type; this consists of a vertical metal cylinder, which slopes off in a conical shoot at the bottom. Inside the cylinder are plates placed horizontally, one above the other, and spaced equally. The plates are made with a slot extending from the centre to the circumference, and also with a circular hole cut out of the centre. A shaft passes down the centre of the cylinder, and arms attached to the shaft extend over the plates. Each arm is set to clear the plate at a greater distance than the others, and on rotating the shaft these arms cause the chips to travel circum-

ferentially round the plate until the slot is reached, when the wood falls to the next lower plate, and so on. The length of travel and speed are maintained at the correct rate to carbonise the wood thoroughly. The charcoal is collected in air-tight receptacles at the shoot. The gases pass up the annular central passage around the shaft (the coolest portion inside the retort) and out at the top of the condenser.

Heat is applied to all these different retorts by means of fuel burned in a brick-work furnace setting, the hot furnace gases passing round the retorts by means of various flue arrangements, each individual installation seemingly having been erected according to a different idea of heating. This is rather unfortunate in its results, as the author is aware from commercial operating tests and laboratory experiments that temperature control and the resultant regulation of the decomposition of the wood by controlling temperatures in the retort has a material effect on the yields of products obtained. Many operators have carried out experiments with this end in view, but probably the most important and convincing are the result of commercial tests carried out for the U.S. Forest Service by R. C. Palmer ("The effect of temperature control on the destructive distillation of hardwood"; see this J., 1915, 898). In his experiments Palmer showed conclusively that by keeping the temperature of the retort as low as possible at the point at which exothermic reaction takes place (275° C.), this reaction could be spread out over a longer time and, therefore, less decomposition of the prime products would take place. The greatest increase in yield was shown to be that of wood alcohol, the resulting increase being 30% over that obtained in uncontrolled operations. The increase in acetic acid (or acetate of lime) was only about 14% under the best conditions.

Any exothermic chemical reaction is naturally more or less difficult to control, the more so when it takes place at a relatively high initial temperature. Another well-known chemical phenomenon bearing on the matter is the tendency of materials in a finely-divided condition to respond to treatment or to react more readily than similar materials in homogeneous masses. Applying these two facts to the distillation of hardwood chips in continuous mechanical retorts, we are immediately faced in practice with conditions which are exactly the reverse of what might be desired for obtaining the most satisfactory results. In the first place the critical temperature, or the point at which the exothermic reaction takes place, is about 275° C., and until this temperature and the resultant decomposition reaction are reached and completed, only 25–30% of the total acetic acid and alcohol will be produced. In the second place there is, instead of a comparatively large and solid piece of wood exposing, say, a unit of surface to the reaction, an extremely large number of small pieces exposing many times the unit surface to the reaction, and consequently reacting individually almost spontaneously. As a result of such uncontrolled distillation mechanical retorts would be expected to give yields considerably lower in alcohol and slightly lower in acetic acid than are obtained in retorts using cordwood or similar material. This is exactly what happens in commercial practice, as the yields in even the most efficiently operated of the mechanical retort plants are as regards wood alcohol nearly 50% less, and as regards acetic acid slightly more than 10% less than those obtained in cordwood retort factories.

In the completion of the destructive distillation of wood there is formed a certain amount of non-condensable gas. Some of this gas is the natural result of the decomposition of the wood, but in addition some is formed by the decomposition of the condensable products formed, due to superheating, etc. If a charge be overheated

at the critical point it sometimes gets out of control, and there occurs what is known as a "blow" of gas. Under these conditions the exothermic reaction proceeds very rapidly, causing a rapid rise in temperature and giving off the products in an excessive amount per given unit of time. The retort and the material inside it being overheated, a large amount of decomposition of the usually condensable products takes place, and in consequence an excessive amount of non-condensable gas is formed. As it is the practice in some plants to burn the non-condensable gas in the fire box for assisting in heating the retort, it can be seen that under certain conditions a vicious circle of excess heat—excess gas—more excess heat may be formed. In mechanical retorts this critical temperature is being reached in certain parts continuously, hence there is a continuous supply of gas for burning. This fact led to an incident in my experience some months ago, when I was investigating conditions at a factory, with a view to a reorganisation and bringing the equipment up to date. I found that the yields of wood alcohol and acetic acid, the former, particularly, were extremely low. The reason for this proved to be that a very small amount of fuel was used for heating, the gas from the retort doing most of the firing, so that they were working at greatly excessive temperatures, overheating the retort and decomposing the alcohol and acid into firing gases, which when burned caused more excessive heating. In other words, they were operating what might be called a gas-producer instead of a retort for low temperature distillation.

The cordwood retort process has had a slow but positive development dating from the period of commencement of more extensive by-product production. The retorts themselves were originally cast-iron cylinders, about 3 ft. 6 in. diam., by 8 or 9 ft., long, with a door bolted at one end and the vapour outlet at the dead end. Working at the temperatures required, and with the rapid heating and cooling which took place in the system, these naturally had a very precarious existence, and great trouble was experienced with cracks, resulting sometimes in disastrous explosions. Gradually the cast iron retorts were replaced by steel plate cylinders, having cast iron doors, and these were set up so that they could be revolved if the side in contact with the fire became burned, thus exposing a fresh surface and giving considerable extension of life. From this type, the next step was to the rectangular steel oven of large capacity, into which the wood was charged on the trucks. This practice gradually became almost universal where comparatively large quantities of wood were used, as the labour and time saved in charging and discharging were enormous. At first these large retorts were merely oblong boxes resting on brick piers, with rollers to allow for expansion. Present-day developments have altered the contour of the retorts to prevent the escape of the vapours more easily, and these retorts are now suspended in the furnaces, expansion being allowed for by the play of the hangers.

The arrangement of furnace flues has also been the subject of many improvements. The original retort was merely set over a fire, the flames playing on and around it. Later a baffle was interposed between the flame and the retort, and gradually the present practice developed of entirely removing fire from the vicinity of the metal retort by means of arches, with positive circulation of the furnace gases around the retort in a manner best suited to the efficient utilisation of their heat.

German and Austrian practice is distinct in that nearly all the retorts, both of small capacity and large, are cylindrical in shape, and are fitted

with an extremely complicated system of flues. The majority of the German and Austrian retorts are of small capacity (not exceeding 2 cords each). Swedish retorts, on the other hand, while showing the result of German origin, are of large size (10—15 tons each) and present several interesting departures in design. The principal one is known as the Gröndal retort, and is of large capacity, but is built in three sections, each isolated from the other and from the air by doors. The first section is the drying and preheating chamber, where the wood is dried; after remaining in this chamber a certain time the truck is removed into the central chamber and is replaced in the drying chamber by a fresh truck of wood. In the central chamber distillation is completed, after a certain number of hours, and the truck moves into the final chamber where the charcoal is cooled, finally being replaced by the following truck on its discharge into the open. The difficulties met in operating this type of retort are mainly mechanical, owing to the trouble in obtaining complete and perfect isolation of the interior chambers.

The present American practice is almost entirely confined to large retorts, having capacities of from 12—20 tons per charge. Most of the plants have daily capacities of not less than 24 tons of wood, the average probably being about 48 cords of 30 cwt. to 2 tons each. A few plants distil as much as 150 tons per day. In recent years many efforts have been made by German engineers and plant manufacturers to introduce into American works, types of apparatus and retort systems which had been developed in German works. One of the large operating companies was induced to make an installation of German equipment, and after spending more than £20,000 on it, the process proved entirely unsuitable to American conditions, besides being in some of its principal features scientifically unsound.

The tendency in Great Britain, on the other hand, has been almost entirely along the lines of small retorts and small capacity, most plants here treating not more than 6 to 10 tons per day in $1\frac{1}{2}$ -ton retorts. This tendency is, of course, due mainly to the limited supply of wood available in any particular district, and also to the limited attention given to the disposal of products, each producer being apparently satisfied to sell his production in a more or less local market. The first step in the installation of the large retort plants was taken by the Government, who put down a plant of the Continental type, to deal with the coppice and cuttings from the Forest of Dean, controlled by the Office of Woods and Forests. The retort is of the cylindrical type, and treats about 10 cords of wood at a charge, and is fitted with Meyer's so-called "tar separator" and the usual condensing system for the acid vapours.

With the advent of the war, the increasing demand for the products of wood distillation in Great Britain, coupled with the cessation of the Continental supply, caused a considerable shortage. Consequently new installations began to appear and old works were enlarged. One or two idle works were rebuilt and enlarged to meet the demands of the moment, and the industry as a whole took a new lease of life. Very naturally the new installations, particularly as they were mostly on a larger scale than the average plant heretofore operated here, were installed along the lines of American and Canadian experience; the smaller plants, recognising the tendency, also adopted the larger scale plan equipment modified to suit their requirements, so that the present condition of the industry shows two distinct types of retort equipment. On the one hand there is a considerable number of plants using the small retorts, while in the larger plants are installed the ultra-modern type of oven retorts.

The present-day equipment in Great Britain is thus a result not only of the slow evolution of the original retort in this country alone, but is also the result of the development which has taken place in other countries in which the industry is and has been a thriving one.

The retort, being the point at which the products are formed, is without doubt the most vital part of the equipment. Unfortunately the development and improvements in refining equipment and methods have progressed far in advance of those in connection with retorts. Possibly this has been due to the fact that the need of improved refining methods was so obvious; nevertheless the fact still remains that the yields of products from the wood in the retorts to-day lack a great deal of reaching the figures which might be expected from a theoretical consideration of the chemical composition and structure of wood substance.

I am soon starting some large-scale tests along certain lines, after having carried out small-scale experiments the results of which indicate that it is possible nearly to double the output from a given weight of wood in commercial plants.

The type of condenser attached to the original retorts was in nearly all cases a series of large straight copper pipes, passing through troughs or boxes and surrounded with water. No particular method of calculation or design seems to have been adopted—each works copying the original. At various times some operator would add a length of pipe and find that he condensed more products, after which this lengthened size was copied by the others. After the introduction of large retorts a more compact system was necessary, and the result was the construction of the tubular surface condenser, in which the vapour passed through the tubes and was cooled by water circulated in a wooden or iron shell. The small retort plants later saw the advantages of this condenser, and it is now rapidly replacing the older pipe types in this country.

The original products sought in wood distillation were the acetates and acetic acid, little or no demand for wood alcohol existing for many years. The original refining equipment, therefore, consisted of a simple copper still heated by fire, with a coil condenser. The resulting liquor was either shipped as made, or certain metals or salts were dissolved in it to produce the required acetates, which were sometimes evaporated before shipment. These acetates, if dried, were dried in open pans over direct fire.

Later, when the demand for alcohol grew, the liquid that came over first in the distillation was collected separately and redistilled several times to obtain spirit, great difficulty being met in freeing the final product from esters, acetone, etc., due to the acid distillation. In more recent years the once-distilled liquid has been neutralised and then distilled for alcohol, but even this process required four, five, and sometimes six distinct distillations in order to obtain a refined product. Until about 1895 very few plants made use of any kind of rectifying head or column, one or two using a series of water-cooled or air-cooled pots in the final distillation through which the vapours were passed. In every case, however, the acetate liquor was boiled down in open pans, and all distillation was by direct fire.

From this time advancement became rapid. Column stills, first of a crude type, came into use, steam heating coils were introduced for all distilling purposes, thus eliminating many dangers and reducing decomposition, more efficient means of testing the products were adopted, and gradually the refinery came under chemical control. At this period, when by reason of more perfect refining of the crude liquors, a better and

more uniform product was obtained, certain substances were eliminated from the products. These substances became known and used, so that new products began to be recovered, forming an additional source of revenue to the plant from materials formerly considered detrimental waste.

After that period we arrive at the present-day procedure, and find the plants either equipped or equipping themselves with apparatus which enables them to make thorough separation of any or all components of the crude liquors and to produce these components as refined products. During the past ten years the tendency, aside from purely chemical development, has been to alter the equipment in such manner as would economise in fuel and labour in order to meet modern industrial conditions.

The greatest scope for increasing efficiency, both chemical and mechanical, naturally lies at the door of the larger works; and it is in these large works that the most improved equipment is found. The small works of to-day, as of yesterday, present inherent difficulties in the way of efficient operation, owing to the bulk of raw material and comparatively small quantity of product. However, it is pleasing to note that many of the small plants have realised that their path to efficiency lies in the line of that type of equipment for the production of the highest-priced products with the minimum of labour and fuel. The large plants, in replying to the call for industrial efficiency, show wonderful results. When a plant treats many tons of wood per day, even an increased production of a fraction of a gallon per ton, the saving of a few pounds of coal per ton, or the development of a new product, means the addition of no mean sum on the right side of the balance-sheet of a year's operation. Present-day refining equipment has, in fine, to mention only a few of the many points of advancement, added some half dozen prime commercial products to the output, elevated the quality of all the products made as compared with those of a score of years ago, and at the same time reduced the fuel requirements in some cases more than two-thirds.

The purposes of the refinery are roughly, first, to separate easily volatile substances from the tarry matter in solution, second, to separate the acids from the alcohols and oils, and finally to eliminate the water from all. When it is remembered that the crude liquor as supplied to the refinery is about 80% water, it is obvious that the principal requirement is economical evaporation. A multiplicity of secondary or subsidiary actions must also take place, and modern design of apparatus has combined many of these subsidiary steps and eliminated others, using the heat developed in one distillation as a source of heat for a subsequent step, and making use of gravity where possible, so that now the entire process of refining is made continuous wherever possible, and the liquors receive the minimum number of distinct "handlings" before being finished. With every separate distillation, agitation, or "handling" of the liquid some small amount of the product is liable to be lost or destroyed, the quantity varying with the type of equipment. To indicate the high degree of perfection of the latest equipment, I have operating records which show a daily production efficiency of 98–99½% of the theoretical. Another and a very marked instance of the effect of installing efficient equipment was the recent reconstruction of a refinery. This refinery dealt with approximately 3000 gallons per day. Substituting one continuous type of refining still with preheater for the old 3-still periodic system, and a triple-effect evaporator instead of open pans for acetate liquor, produced a more reliable product and reduced the steam

consumption from 38,200 lb. to 10,700 lb. for this particular department.

The yields of what I will call prime products, viz., charcoal, 80% acetate of lime, 95% refined wood naphtha (including esters and ketones), and dry tar, present a fruitful field of research, and have been the basis of a great many experiments. Unfortunately commercial yields obtained from different countries or even different plants have such widely different bases of computation that they cannot be used for comparative purposes. "Yields per cord" or "Yields per ton of wood as charged" mean nothing whatever, as a cord may be anything from 64 cub. ft. stacked to 256 cub. ft., depending on the country and district referred to, and cords of wood of 128 cub. ft. may vary in actual weight more than 100% and still contain very nearly the same weight of water-free wood. I have carefully correlated in Table II. some records of yields obtained in various plants which have come under my experience, and in addition have tabulated yields obtained in American practice, and in experimental operations as collected personally and by other investigators. In each case the actual yields of commercial products have been calculated to production per ton (2240 lb.) of water-free wood carbonised.

wood in mechanical retorts lies, as has been mentioned, in the production of gas at the expense of products, as well as in the fact that the chippings are usually in a very dry condition.

While on the subject of yields it is necessary to point out some of the factors that have a strong influence on the yields obtained in practice. The first point that naturally arises is that of species. All hardwoods do not give exactly similar yields of products, although taken weight for weight there are not many striking differences. The principal differences make themselves evident in the alcohol and tar yields, which may be considered to be due to the composition of the wood itself.

The following results are based on small scale experiments only, but all were carried out under similar conditions, so that they are comparable.

The methods of determining the various products were as follows:—

Acetic acid. The crude liquor was distilled until the residue in the flask became heavy, followed by steam distillation until the resultant distillate tested only 1% acid on titration of 5 c.c. The whole was well mixed and 5 c.c. taken for titration with $N/2$ NaOH.

Wood alcohol. The above distillate was fractionated three times over lime and the sp. gr. of

‡ The actual production tests 84–86% acetate.

§ The actual production tests 75–78% acetate.

Even this tabulation should not be taken as indicating the comparative overall efficiencies of the several types of plants, owing to the variation in moisture content, size of wood, and species used in the average materials of the several countries and plants. Broadly considered, however, these figures serve to bear out my remarks on the effect of control of reaction and the size and condition of wood. The reasons for the marked difference in fuel consumption per ton of actual dry wood carbonised in British practice as compared with American, may be found in the fact that the average moisture content of wood in Great Britain is nearly double that of average American wood, and also in the fact that a cord of British wood as charged is made up of pieces of smaller diameter, so that the weight per cord as charged is only about 1½ tons as against nearly 2 tons. Under the practical conditions of distillation, there is a large amount of excess heat supplied to a retort, consequently in distilling two charges of dry wood in equal sized retorts, one occupying considerably less bulk than the other, and of consequent different weights, only slightly different amounts of coal will be used, the excess being necessary for heating the brickwork, radiation losses, etc. It will readily be understood, therefore, why in plants which are favoured with heavy, dry wood, the fuel requirement per ton of dry wood carbonised is less than in similar plants where more bulky wood is used. The reason for the low fuel consumption per ton of

the final distillate determined on a Westphal balance and calculated to methyl alcohol.

Tar. The residue from the first distillation of crude liquor was weighed. Several tests of this tar indicated that it contained about 0.5% acetic acid, but this quantity was neglected in the calculation of acid produced.

The figures in Table III indicate broadly that the best wood for producing acetate of lime is the birch, which yields about 20% more than the average of the six species. On the other hand, for the best production of alcohol, we must turn to the maple, which is again some 20% better than the average.

Another factor which, in commercial operation, particularly, may have an important bearing on the yields, is the moisture content of the wood. The mere fact that water is present in the wood does not of itself necessarily reduce the yield per ton of dry wood present. If a wet charge be heated carefully, and due precautions taken that the drying operation is complete before decomposition begins, then no serious losses need result. If, on the other hand, the charge is fired carelessly and the exothermic point reached before the moisture is eliminated, a condition exists which offers a very favourable opportunity for the setting up of side reactions. In other words, there is a high temperature, possibly slight pressure, and products in their nascent state in the presence of steam. The decomposing effect of steam on many nascent substances is well

* Hawley and Palmer (*loc. cit.*).

known, although superheated steam is not quite so active under all conditions as saturated steam. However, that saturated steam is present must be admitted, as the moisture at the instant it is formed into steam in the wood is saturated, before it can become superheated. This theory I have never specifically proved by experiment, but it is the result of observation in commercial experience. In distilling wet wood I have many times noticed that if the exothermic point is reached too quickly, a greatly increased amount of gas extending over a much longer period is generated, with a correspondingly decreased flow of liquor. If, on the other hand, the moisture is eliminated before the reaction takes place, the decomposition may be easily regulated and the gas production proceeds normally.

It is in this connection that British operating conditions are more difficult than American, as well as in the fact that the majority of wood used in this country is smaller in diameter than the average American cordwood, and consequently more difficult to control during decomposition.

Another factor which has a very considerable bearing on the fluctuation in the yields is the variation in heating, and to a lesser extent the actual temperature itself. The attaining of high temperatures during a distillation does not necessarily mean that extremely low yields will result, although in those industrial plants where the attaining of high temperatures is a common practice, it has been noticed that the yields have been rather lower than the average. The reason for this is that where excessive temperatures are the rule, there is little attempt made to control the period at which high temperatures occur, and this time factor is most important in connection with temperature. For instance, a retort charge may be fired so slowly during the first portion of the distillation (that is, during the time when water is being driven off) that in order to complete the charge in the 24-hour cycle, it is necessary to rush the last portion. This entails excessive firing during the exothermic reaction and after it, which, of course, means decomposition or "cracking" of a portion of the vapours as formed. Another charge, uncontrolled, may be fired too heavily at the start and reach the exothermic point before the operator is aware of the fact. The heavy fire causes the decomposition to proceed too violently, and again overheating results, with consequent decomposition of products. On the other hand, if a charge be fired carefully at the point of reaction, and for some time afterwards, permitting only a gradual rise of temperature at the exothermic

point, it may be "finished" to a very high temperature without undue decomposition because the "spontaneous" decomposing point is passed and the balance of the reaction may be termed endothermic. The proper method of heating may be quite accurately plotted. A sample time and temperature curve (fig. 1) for normal distillation is shown herewith (curve A) and alongside it is plotted a sample "uncontrolled" run (curve B). A comparison of these curves will illustrate clearly the above remarks. The uncontrolled curve, B, indicates a continual firing, with consequent rapid rise to the exothermic point, but instead of reducing the external heat at this point the temperature continues to a marked maximum and declines rapidly, indicating that the reaction has

Time v. temperature.

taken place in a minimum time and with consequent increased intensity. In the charge which was fired carefully (curve A), on the other hand, the exothermic point was anticipated by easing off the fire, and the reaction spread over several hours at a minimum temperature. When the reaction had practically ceased, one or two hours' additional hard firing completed the distillation and finished the charcoal to hard and lustrous black. Of two similar charges of wood distilled, as indicated in the respective curves, the "controlled" distillation produced 1580 gallons of crude liquor, equivalent to 1785 lb. of 80% acetate of lime, while the "uncontrolled" charge produced 1300 gallons of liquor, equivalent to 1429 lb. of 80% acetate of lime. Another curious occurrence noticed in connection with high temperature during exothermic reaction, is that the content of ketones in the spirit is considerably increased. This might naturally be expected owing to the decomposition of acetic acid. The so-called "acetone" content (ketones determined by the iodoform test) of the first runnings from the rectifying stills has been varied from as low as 17% to as high as 23.5% by variation of the heating of the retorts.

Operating methods and equipment.

With regard to the retorts, the mechanical type is operated at a disadvantage due, to the fact that all the steps of removing moisture, decomposition, etc., are taking place simultaneously and continually. There is certainly, however, some fixed temperature or condition in the retort at which it is most advantageous to work in order to obtain the largest yields of both acid and alcohol. What this condition or temperature is I am unable from experience to say, but from a theoretical standpoint it would seem advantageous to have the operation in two distinct and separate stages, each stage being conducted in a separate retort or portion of retort, with separate means of firing and control. The practical objections to such a method may be overwhelming, but the idea is advanced as a suggestion for future experiments.

The cordwood retort is not only very easily operated, but produces its own indicator in the liquor, which tells plainly every change which is taking place in the interior. Although many retorts are fitted with pyrometers for the guidance of the operators, after a few months the men become expert at reading the liquor colours, and can actually anticipate the reactions as accurately as with the pyrometers. The recording pyrometer is to be preferred to other types, as a permanent record is automatically made which cannot be evaded, whereas workmen have been known to disregard liquor changes with results detrimental to the plant as well as process.

The operation of retorts is or may be governed largely by the condensers for the vapours attached to them. Condensers may be built of maximum or minimum capacity for a retort. I think it a distinct advantage from the operating point of view to have them of minimum size. A condenser made of maximum capacity for a given retort is made in reality large enough to care for the greatest volume of vapours that such a retort may ever produce. This means, in other words, that no matter how careless the operators may be, no matter how much overheating occurs, with consequent decomposition and excess gas formation, there will never be a "blow" of gas, that is, the condensers will account for it all, and no external evidence will be available to call the attention of the man in charge to what is going on in the retort. If, on the other hand, the condenser be of minimum size, that is, large enough thoroughly to condense and cool all the condensable products from the retort under most efficient conditions of working, then, if through carelessness or for whatever reason, excessive gas is formed, it will immediately become noticeable to anyone in the factory, and can be corrected within half an hour or so. Instead of per-

mitting careless or inefficient operation, the minimum sized condenser makes it imperative that the retort be carefully attended.

A certain amount of the reduction of yields from what may be called the "theoretical" is undoubtedly due to decomposition of vapours where they are in contact with the retort itself and the hot wood, in their passage to the condenser. To obviate this in some degree, retorts have been fitted with two, three, and sometimes four condensers attached at various points. This lessens the length of travel for the average particle of vapour from its point of formation to the outlet, and certainly increase in yields has followed the adoption of this practice. The question is principally one of economies, or, in other words, does the increase in efficiency pay for the increased capital expenditure and attendant multiplication of cleaning troubles? Our experience tends to the opinion that the most economical installation in the nominal 12-ton capacity retort embodies two condensers. One difficulty which has become evident occasionally in retorts fitted with two condensers is that of persuading the vapours to pass to both of the condensers in approximately

Time v. rate of flow.

Time in hours; retort charge—12 tons.

CURVE II.

equal amounts. There have been times when, without any apparent reason, the entire volume of vapours from a retort has passed through one of the condensers while no condensate has been obtained from the other one. With no alteration or cleaning, the next charge behaved normally, the condensers taking approximately equal portions of vapour.

The purpose of the condenser equipment is to condense the vapours to liquids, and to cool these liquids to as low a temperature as possible. The presence of volatile products renders it vital to successful recovery that the liquor be cooled as nearly as possible to atmospheric temperature. It is during the time of the exothermic reaction, with its consequent heavy flow of liquor and non-condensable gas, that the concentration of the acid, alcohol, and oils in the liquor is

TABLE IV.

Liquor. temp.		Acetic acid per 100 c.c. condensate.	Alcohol per 100 c.c. condensate.	Acid lost per 100 c.c. condensate.	Alcohol lost per 100 c.c. condensate.	% of lost acid recovered in scrubber.	% of lost alcohol recovered in scrubber.

54.5	130	9.9	2.52	2.1	—	—	—

highest, so that any increase in liquor temperature at this point gives full opportunity for the greatest loss of product.

Table IV, indicates the total loss of acetic acid and alcohol that takes place where the gas is not passed through a scrubber after leaving the condensers, if the liquor temperature is allowed to reach the respective figures.

In addition I have appended to the table the proportion of the products (acid and alcohol) recovered by scrubbing the non-condensable gases after leaving the condenser at these temperatures.

Fig. 3 shows the percentage losses of alcohol (A) and acetic acid (B) plotted against the temperatures of liquor. It will be noticed that the loss of alcohol does not increase directly with the increase in temperature, so that the curve A is a very unusual one. There appears to be a period between 38° and 55° C., after a rapid initial loss of about 40%, at which the percentage loss remains fairly stationary; then as the boiling point of the alcohol is approached the percentage

Per cent. loss v. Liquor temperature.

Liquor temperature.
CURVE III.

loss rapidly approaches 100. It is possible that the acid curve proceeds in the same manner, but owing to the practical difficulties encountered in operation of commercial units the temperature could not be permitted to reach more than 60°C. It will be seen that suitable scrubbing arrangements are almost a *sine quâ non* in connection with condensing equipment, as even with excessive liquor temperatures a considerable quantity of product is recovered that would otherwise be used as fuel. Since between 60 and 80% of the total production of acetic acid and alcohol is produced during the exothermic reaction, the importance of low temperature of condensate and auxiliary scrubbing apparatus is apparent.

The products of carbonisation must be condensed from a temperature somewhere about 350° C., or higher, to atmospheric temperature to obtain crude liquor. As the subsequent refining involves distillation, evaporation, etc., it has been the aim of many designers and investigators to eliminate the first condensation, and utilise the heat present at this stage to perform certain of these secondary operations. On standing, a large portion of the heavy tars separates out from the crude liquor, leaving a supernatant layer of acid and alcohol in water. This watery layer, being acid, naturally carries a certain amount of tarry matter in solution. In order to produce a grey acetate of lime and a colourless

wood alcohol, it is essential that this dissolved tarry matter be eliminated. This has usually been effected by simple distillation, the water, acid, and alcohol passing over as vapour and the tar remaining as residue. The principal systems for eliminating this distillation of liquor were developed in Germany and are known as Meyer's and Jørgensen's systems respectively. Both operate along similar lines, and both have met with a certain amount of commercial success. However they are both basically wrong in conception, and have met with practically no success in operation outside of the Central Empires. The system is based on the idea that by requiring the hot vapours as they leave the retort to bubble through several layers of hot tars, the tarry matter will be collected and the resultant vapours, after condensing, will be watery distillate of acid and alcohol freed from the dissolved tarry substances. Viewed superficially this would appear quite a satisfactory arrangement, and it must be admitted that in practice some such actual result is obtained, that is, the tar is separated and the distillate is condensed in such condition that grey acetate of lime can be produced from it without further distillation of the acid. When that is said, then all is said for the process, for it is impossible to produce colourless alcohol from the liquor by the usual methods, and in addition the oils and resinous matter present cause an excessive amount of lime sludge to be formed after neutralising.

Where the idea is fundamentally erroneous is in the fact that by causing the hot gases to bubble through hot, liquid tarry matter, every opportunity is provided for the interaction of the substances present, with the consequent formation of condensation products, such as phenol-aldehyde resins, acetyl compounds, and methyl-phenol compounds. These formations naturally result in decreased yields of prime products, which is in itself to be deplored. Then, too, the introduction of the necessary apparatus causes a back pressure to be put on the retort, and an exhaust fan is necessary. This in turn tends to increase the speed of travel of the gases, with increased entrainment losses. The most promising process lies along the lines of fractional or even differential condensation of the heavier substances. The result of experiments on this line has been the production of a system of separation which shows every promise of meeting the requirements of present-day operation, without the difficulties present in the above-mentioned system. In this new system, which is being protected by the necessary patent, the vapours are passed through a two-stage cooler in which the heavy tars are condensed differentially and removed immediately from contact with the gases. The remaining vapours, consisting of water, acid, alcohols, and some light tar oils, then pass to a final separator in the form of a rectifying column, in which the tar oils by reason of their higher boiling points are eliminated at temperatures just above the boiling point of water, the final condensate being a clear liquor slightly tinged with yellow, which differs in practically no respect from the white acid obtained by ordinary distillation of the crude liquors. It is quite possible to make use of the remaining heat of the vapours before condensing to separate the alcohols, but we have not found this to be profitable on a small scale, in view of the highly efficient rectifying plant available under present conditions.

The detailed consideration of refinery practice and equipment for producing the prime products as well as the derived and secondary products must be left to another paper.

Great Britain's pre-war requirements of wood distillation products have been summarised, and mention made of the impossibility of increasing

the native industry sufficiently to account for the necessary quantities. The magnitude of any future development depends on the degree of acceptance by the Government or by private owners of a suitable and complete scheme of afforestation and forestry control. Whenever the laws of scientific forestry have been allowed to control timber lands, such lands have become a source of profit to the State or the owner, directly as well as indirectly.

Possibly the most serious difficulty to be met, as has been the experience of most other countries, will be the suitable and profitable disposal of the charcoal. Every effort should be made by the associated producers to develop new markets or uses for this material.

The inauguration of a scheme of forestry on a national scale requires time, so that to satisfy immediate requirements, the timber resources of the Colonies must be called into use. In this respect the Empire resources may be said to be inexhaustible. Canada already has her industry established. South Africa has available an unmeasured quantity of wattle wood (*mimosa*), of which a great amount is at present waste material from tannin extract factories, for the bark only is used for this purpose, the wood being left or burned. Australia, with her present timber industry, has available enormous quantities of lumber and sawmill waste suitable for distillation. Here, also, the demand for wood oils, for flotation of zinc and other ores, brings an active market at the distillers' door. India, the Federated Malay States, Borneo, etc., all have unlimited quantities of wood, and have markets locally for many of the products, such as charcoal, acetic acid for rubber coagulation, tars for disinfectants, etc. Japan extends an open market for the various products in which these Colonies and countries would have a great shipping advantage. It may be said, therefore, that the Colonies offer an exceptional field for the immediate development of the industry, and as only very crude labour is necessary for most of the departments, Colonial conditions present distinct advantages for successful commercial operation. We may look, therefore, to these countries supplying our markets in the near future with the 50% production that previously came from Germany and Austria.

DISCUSSION.

Mr. W. D. A. Bost said that, with reference to the yields obtained in mechanical retort plants, the figures presented did not agree with those given by Haig (this Journal, 1890, 1120). With regard to the differences in products from pine woods and hardwoods, he pointed out that in the former the oils and resins were present in the wood and were merely driven off by the heat, while in the latter the products were formed from the decomposition of the wood substance itself.

Prior to the war, some 2000 tons of charcoal had been imported annually, but now the home production had been increased by about 15,000 tons, so that the post-war disposal of this excess would be a serious matter.

Professor T. GRAY enquired as to the point at which the vapour temperatures of the retorts were taken, and pointed out that the apparent temperature might be higher or lower than the actual temperature, due to radiation from the brickwork, etc., which raised the question as to whether 275° C. was the actual temperature of exothermic decomposition. He enquired if it were not practicable to use several retort outlets, connecting them to one condenser, thus overcoming the tendency for the gases to travel unequally to the two.

The CHAIRMAN enquired as to the effect of injecting steam in wood distillation.

Mr. LAWRENCE, in reply, said that the figures

given for yields covered several types of mechanical plants, not the worst nor the best being taken for the comparative purpose. The temperatures were in nearly all cases taken in the vapour outlet from the retort, before the gases reached the condenser. The vapour outlet was very short, but as the distillation was carried out at a comparatively low temperature the brickwork should not materially affect the readings, as the pyrometer couple was entirely immersed in the flowing gas. The temperature inside the retort itself was probably higher than that shown by taking the temperature of the vapours at the outlet, but knowing the indications of the exothermic point, as shown in the colour of liquor, any arbitrary temperature curve would serve the purpose of control. The temperature of the flue gases at the chimney was usually about 100° C. higher than the retort gas temperatures. The exothermic point, 275° C., had been determined experimentally by many investigators, notably P. Klason and others. The reason for not connecting several outlets to one condenser was the trouble experienced in choking of pipes when exposed to the air for any distance before reaching the condenser. He had seen a 30-in. bore pipe completely choked in a very few weeks where it was only about 6 ft. long between retort and condenser. The use of steam in the retorts during wood distillation had been tried with a view to clearing the gases out more rapidly, but the result had been adverse, due to decomposition and to the dilution of the liquors. Probably the increased yields when steam was used with coal, were attributable to the high temperature at which the distillation was carried out. In wood distillation the products were nearly all soluble in water and the water must be evaporated. That was not so much the case in coal distillation products.

MR. H. PEILE IN THE CHAIR.

THE MELTING POINT OF COAL ASH.

BY J. T. DUNN, D.S.C.

In 1913 it became necessary to ascertain the melting points of the ash of a number of samples of coal for certain industrial purposes. There proved to be so much variation amongst them that it was decided to investigate the matter further. The ashes were accordingly analysed, and gave the figures tabulated on page 16T, columns 2 to 17. As a matter of interest, the figures in columns 1 and 18 have been added. The ashes are arranged in ascending order of melting point, and the letters, N, D, S, indicate respectively Northumberland, Durham, and West of Scotland coals. The temperatures were taken by a thermoelectric pyrometer and also by Seger cones, but are not to be regarded as accurate within 10° or 20° C. Alkali was taken by difference, except where marked "d," in which cases it was determined.

Further work on these has been stopped by the pressure of more urgent professional work, and the analytical figures are now presented as a matter of interest. Half a century ago, Richters made a very elaborate and interesting pioneer investigation of refractory materials (fireclays), and inquired into the conditions under which their melting points varied. He arrived, empirically, at results some of which are now known to be typical of the general behaviour of mixtures of more or less fusible substances. He found that, if alumina and silica were melted together, the

melting point of the mixture became lower on passing from pure silica to more and more alumina and then rose again until it reached the point of pure alumina. He further examined the effects of different weights of different basic oxides and came to the conclusion that the effect produced upon the melting point was determined by the quantity of the basic oxide which was added and its molecular weight, so that, if one adds to a given

DISCUSSION.

Prof. HENRY LOUIS suggested that a good deal of progress had been made in such matters since Richters' time, and he did not think they could accept his theories as correct. Lead oxide, for instance, lowered greatly the fusion points of silicates. Furthermore the question of the state of oxidation of the iron in the ash was a vital point. Ferrous silicate was a very easily fusible substance, whereas

mixture of alumina and silica a quantity of another metallic oxide, the amount by which the melting point is lowered is almost independent of the nature of the material, provided that its quantity is proportionate to its molecular weight, and that, if a number of different oxides are mixed together with the alumina and silica mixture at the same time, the reduction of the melting point depends upon the number of molecules of the oxides which have been added to the given number of molecules of alumina and silica.

Calculating the above analyses to molecules, and taking the number of molecules of alumina and of other basic oxides associated with 1000 molecules of silica, the following figures are obtained:—

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
Mol. of alumina	382	314	391	426	402	420	405	455	435	453	391	400	499	443	422	389	410	485

It will be seen from them that, whilst by no means always accordant with Richters' rule, they do indicate in general that the melting point rises as the relative proportion of basic oxides diminishes.

Attention may be drawn to Nos. 1 and 18. No. 1 is the ash of a Natal coal, and of the total lime (22.80%), 6.24% is present as sulphate, 2.0% as phosphate, and nearly 6% as quicklime (due of course to carbonate in the original coal). The silicates thus form only about 75% of the total ash. No. 18 is the ash of a Spitzbergen coal, perfectly white, and almost identical in composition with a china clay (No. 19 is the analysis, for comparison, of an ignited Cornish china clay). I have no doubt, although I have not had an opportunity of testing it, that this ash would show the same refractoriness as a china clay. The peculiar ash of a Kent coal, which contained only 4% of silica and 80% of ferric oxide—a rich iron ore—is also noteworthy.

These determinations of melting point were made for a briquetting plant for iron ore, where the briquettes are taken in wagons through the furnaces; in the course of this operation considerable trouble resulted when a change of coal was necessary because of the failure of the usual supply, from the ash of the coal with which the furnaces were fired being deposited on the wagons until they clogged up and jammed in the furnace.

ferric silicate (the existence of which was very debatable) would be fusible with difficulty. It was known that magnesia rendered silicates far more infusible than a good many other substances of both higher and lower molecular weight, so that the problem could not be worked on the lines suggested by Dr. Dunn. He thought that the modern view was that each silicate had its own melting point, and in the case of complex silicates silicates formed eutectics. The very elaborate work of Prof. Vogt should be consulted. The whole subject was exceedingly complex and could not be disposed of by the simple theory of molecular weight.

Mr. C. H. RIDSDALE said that the fusibility of ash had a very important practical bearing on the use of coal. Dr. Dunn had mentioned one

way in which the coal acted detrimentally, namely, by the ash becoming deposited upon the bogies which carried the briquettes through the furnaces. Another instance was that in raising steam by means of coal that had a very fusible ash, it would soon be found that the grate bars silted up or the air space became reduced and the amount and evaporative power of the fuel that could be burnt would be very much reduced.

Mr. S. H. COLLINS stated that the Board of Agriculture particularly wanted information with reference to the potash content of ashes, and he would be very glad if anyone who knew of any large quantities of coal ash likely to contain potash, even in very small amounts, would inform him. It did not depend upon the percentage of potash in the coal ash but upon the quantity which could be washed out with water. The expense of so washing it out was very small.

Mr. H. DUNFORD SMITH stated that he believed that some of the Continental railway companies had a specification for the melting point of coal ash and that they would not accept a coal with a melting point below 1400° C. for use on their express trains.

Mr. WEYMAN asked whether the temperatures given were those at which the first signs of softening appeared, or those of complete fusion.

Dr. DUNN, in reply, said he entirely agreed with Prof. Louis as to the advances made since Richters' day, although he had, perhaps, given them the impression that nothing had been done since. He had only referred to him as a pioneer. It was quite true that subsequent research had proved that his rule did not hold in every case. The coal-ash cones he used were always allowed to melt completely and the temperature was taken when they had sunk down entirely. It was very noticeable that different coal ashes behaved in very different ways. Some of them melted quickly—like ice, so to speak—whereas others went through a long period of gradually decreasing viscosity and the temperature at which they began to show signs of motion was many degrees below that at which they finally liquefied in a drop or blob at the bottom. Most of these ashes contained anything from 1 to 3% of potash.

The CHAIRMAN remarked that there was no doubt that it was a subject of great importance, especially as regarded the quality of coal used. He did not think it was at all customary for buyers to insist upon a particular melting point of the ash, although it was very important.

MR. JEROME ALEXANDER IN THE CHAIR.

RECOVERY OF POTASH FROM WOOL-SCOURING WASTE.

BY ROBERT SPURR WESTON.

For many years the author has been interested professionally in the engineering and scientific problems connected with the cleaning of rivers, and has devoted a great deal of attention to the disposal of factory wastes, among them wool-scouring waste. Wool-scouring waste is one of the most befouling and greasy liquids which streams receive. If discharged unpurified, it fouls the banks and bottom, and causes the growth of dense masses of aquatic vegetation, which subsequently becomes covered with wool fat, dies, disintegrates, becomes detached from the banks and bottom of the stream, and drifts down to damage the property of riparian owners.

In one bleachery, said to be the largest of its kind in the country, grease spots on the finished cloth caused damages at the rate of several thousand dollars a month, until the wool-scouring waste discharged by three large mills above was purified. In another case, the discharge of wool waste prevented the dyeing of delicate fabrics. In still another, the waste fouled a stream so much as to cause a down-stream mill to shut down a part of its plant until the water could be filtered before use.

The condition of such rivers as the Merrimack, the Blackstone, and the Passaic is too well known to comment upon. Notwithstanding that they are large streams, they are so polluted as to be useless for many industrial purposes unless the water be first purified.

Even when wool-scouring waste is discharged into a sewer connected with municipal disposal works, it will, unless greatly diluted, cause many types of disposal beds, especially intermittent sand filters, to clog rapidly, and to become useless. Hence the difficulty of the sanitary engineering problem of wool-scouring waste disposal. The waste fouls the rivers unless treated, and works designed for the purification of domestic sewage may be unable to dispose of it.

Until the great war, the only practical method of treating wool-scouring waste was to precipitate the solids with sulphuric acid or acid sodium sulphate. The precipitated sludge was then dried on sand beds and the grease recovered from it by pressing in steam-jacketed hydraulic presses. This method produces an acid wool grease or so-called acid dégras; it is now worth 95c. a pound and may be produced for less than 4c. The potash in the supernatant liquor is in the form of sulphate, but the liquor contains much other mineral matter and free acid, and no method has yet been devised to recover the potash economically. The liquor can be discharged into a stream, although filtration may be necessary if the stream be small.

Since the war, the old-fashioned acid or "cracking" process just described has been modified, in this country, chiefly through the efforts of the Du Pont de Nemours Co. The improvement consists first in allowing the waste to flow over solid nitre cake, a cheap and abundant waste product. Then, instead of precipitating the greasy sludge to the bottom of the treating tanks, the waste is so treated in a continuous subsiding basin that the grease rises to the surface in the form of scum. This is skimmed off, the acid neutralised with sodium carbonate, and the whole heated to boiling. The use of soda causes the dirt to separate from the grease and avoids the necessity for presses. The grease and soap are then skimmed off, re-acidified with nitre cake, and the acid grease is clarified by allowing it to stand over acidified water in the usual way. This process produces a very light-coloured grease, and the liquor is of nearly as good character as produced by the old-fashioned process. This continuous acid process, like the older one described above, produces a waste from which potash cannot be recovered economically, unless some method be devised for evaporating the acid liquor. There are other methods of treating wool-scouring waste, however, and many have been known for a long time, but have been considered impracticable on account of the low price of potash. Among the many considered, three main types may be described.

1. *Precipitation process.* This consists in first allowing the waste to settle to remove sand and other settling solids and afterwards passing it through a centrifugal machine to remove the free fat and the finely-divided suspended matter. The solids in the machine effluent are then precipitated by chemicals and the sludge so formed is dried, using filter-presses, or, if necessary, hot-air driers. A low-grade grease is extracted from the sludge and the latter is ground and dried for use as a fertiliser base. The filter-press effluent is then evaporated, the residue calcined in a rotary furnace, and the potash recovered by lixiviation.

2. *Cardem process.* This is a process which has been successfully employed to reduce sulphite pulp liquor and tanning extracts to a powder. The apparatus consists of a series of chambers through which hot flue gases are passed and into which the settled and centrifuged wool-scouring waste is sprayed through special nozzles. The process is carried out in two stages, known as the wet chamber and the dry chamber respectively. If a dry product is to be secured, the concentrated waste from the wet chamber must be degreased by solvents. The dried product, quite hygroscopic, may be used without further treatment or may be calcined and lixiviated to recover the potash.

3. The settled and degreased liquors may be concentrated to a liquid containing 65% of solids, using an evaporator especially designed to prevent foaming and scaling, and the concentrated liquor coked in an open furnace, after which the potash may be removed from the coke by lixiviation. This process is facilitated and made more profitable

by degreasing the concentrated liquor before coking or by washing the wool in naphtha.

It may be noted that in all of the processes just outlined, the first steps are the subsidence of the waste to remove the settling solids, and its passage through a centrifugal machine to remove the free fat and coarser colloidal suspended matter. The degreasing process by itself is profitable. The grease recovered by the machines sells for an average of 10 c. a pound, and the better grease may be used for the manufacture of lanoline, which is now worth 41c. to 46c. a pound. In the author's opinion, it is the centrifugal machine which makes the recovery of potash possible. Former attempts to recover potash from wool-scouring waste failed because of the formation of an impure, vitreous potassium silicate during calcination. The potash in this vitreous silicate is insoluble in water and its recovery from the ash is as difficult and the cost as prohibitive as from a natural silicate. During the last year, cokes the ashes of which contain 95% of soluble matter, consisting almost entirely of potash salts and sodium carbonate, have been produced from settled and centrifuged wastes. During the war, the "potash" produced will contain sodium as an impurity because of the decrease in the use of potash soaps in the wool-scouring process.

Another essential improvement has been made in the mill scouring rooms, where a great saving in water and consequently a greatly increased concentration of both grease and potash has been effected. Except in two cases where the wool is degreased by the naphtha process and subsequently washed in water without soap, the American mills wash the wool in so-called trains of from three to five bowls. Formerly nearly all of the mills used clean water to refill the bowls, but where recovery methods are practised, it is essential that the washing process be conducted on the counter-current principle, that is, the first bowl only should be discharged to waste, and it should be refilled as far as possible from the second bowl, the second from the third, the third from the fourth, etc. Thus the wool and the water will pass through the train of bowls in opposite directions and the minimum of water will be used.

Where potash recovery is practised abroad, the so-called desuinting process is used, that is, the wool is first soaked in water which dissolves the potash, and then the solution is evaporated and calcined. In America, however, this process is seldom used, largely on account of the extra machinery and attention required. Usually the wool and soap with other detergents are introduced into the first scouring bowl, while water alone is used in the remaining bowls. In most mills the contents of the first bowl are used until they become so dirty that they must be changed.

Instead of using alkali and soap in the first bowl, one mill omits the soap and adds it to the second bowl, thus producing a first bowl discharge much more suitable for the recovery of grease and potash than if soap were used. The discharge from the second bowl may be treated by the acid process if the unpurified discharge would injure a stream; otherwise, it would hardly pay to treat it even in war times. Another mill has tried the plan of using over again the settled and centrifuged waste discharged from the first bowl, and has been able to do this three times and still produce a properly scoured wool. The water saved in the first bowl is passed through the end of the train, thus cleaning the wool without diluting the waste. In this way the waste can be concentrated to contain several per cent. of solids. In a few mills water and soap solution are passed continuously through the train of bowls. This would seem to be the ideal method of using water if by-products are to be recovered.

For the recovery of by-products, the best method of washing wool is the naphtha process. Wool which has been washed with naphtha is subsequently washed in water and the waste produced is free from grease and easily concentrated. It can be evaporated to dryness without difficulty and calcined to produce a coke containing as high as 45% of potash.

The various processes outlined have all been tried in practice. The precipitation process is too expensive on account of the large amount of chemicals required to precipitate the suspended matter, and too complicated on account of the fifteen or more distinct operations necessary.

The Cardem process is very promising, and we have tested it quite thoroughly, using the greaseless waste from wool which had been washed with naphtha. Undoubtedly where waste flue gases are available, their use enables the waste to be concentrated more cheaply than by any other process and has the further advantage of causing little loss by entrainment. Unless degreased, the waste cannot be evaporated to a dry, friable mass in this evaporator, and even if the waste from the wet chamber be degreased before its final concentration in the dry chamber, the product is very hygroscopic; consequently it must be coked before it can be used directly as a fertiliser or before it can be lixiviated for the recovery of the carbonate. Where waste heat is available, the wet chamber of the Cardem apparatus can take the place of the multiple-effect evaporator, but if the dry chamber be used the final product ought to be coked, and it may prove best to perform the final evaporation and coking in the same apparatus, usually an open pan, heated by fuel oil.

The process which is usually recommended is to evaporate the machine effluent in a triple-effect of proper design, or in a Cardem wet chamber, degrease the concentrate with an immiscible solvent, distil off the solvent from both aqueous and solvent layers, and then coke the aqueous concentrate in an open pan heated by fuel oil. The concentrated mass takes fire during coking and incinerates to a porous, gray, non-hygroscopic solid, which may be ground and lixiviated for the production of a nearly colourless solution of potassium and sodium carbonates, which is nearly free from silica and from which the potassium salt may be recovered by fractional crystallisation. At present the coke finds a ready market in the fertiliser industry. It usually contains 20% or more of potash as K_2O .

There were many practical difficulties which had to be overcome before the waste products could be recovered economically. The centrifugal machine eliminated the silica, but the evaporation of a soapy, alkaline liquor in an evaporator was a real problem, and for this reason the Cardem apparatus promises a satisfactory solution, although the first cost of the plant plus royalty is higher than the first cost of an evaporator.

The first and second evaporators tried were of the ordinary, tubular type in which the vapour spaces were about twice the usual volume, that is, the effects were nearly twice the usual height. One of these evaporators, having each effect 4.5 feet in diameter, had vapour spaces 9.5 feet high. Notwithstanding these liberal allowances, the liquor foamed so much in the first two effects that it filled the vapour spaces with a mass of bubbles, many of them 6 inches in diameter; this foaming was attended with loss of liquor and low efficiency. The first evaporator tried was about 55% efficient. The second was ordered amply large to make allowance for foaming. It was then learned that the bubbles can only be broken up by high vapour velocities, and at present two evaporators embodying this principle are being tried. One of them is reported to be work-

ing efficiently and economically; the other has not yet been tested.

The evaporation problem has been solved satisfactorily. With proper apparatus, triple-effect or wet chamber, degreased waste may be concentrated to 65% of solids. It is not usually practicable to obtain this concentration in a triple-effect. It is necessary to use a small finishing pan or open kettle for the final concentration, because the boiling point of the waste rises rapidly above concentrations of 55%. In the Cardem process the liquor is sprayed into the chamber, over and over again, until concentrated sufficiently.

The difficulties encountered in degreasing by immiscible solvents are neither unusual nor unfamiliar and are easily overcome. A large ratio of solvent to waste must be used, otherwise the solvent will not separate from the aqueous liquid. No untried apparatus is necessary for the recovery of the grease and the waste product from the evaporator in which the aqueous portion is treated is fluid even at high concentrations.

As mentioned previously, the degreased liquor may be concentrated to 65% of solids. One sample of evaporator concentrate which had not been degreased had the following composition: sp. gr., 1.158; b. pt., 104.3° C.; total solids, 37.1%; ash, 15.5%; fats (by ether), 5.9%; potash (K_2O), 7.0%. This analysis represents the minimum degree of concentration which is practicable. The process of degreasing reduces the water content and the residual potash liquor may then have the following composition: sp. gr., 1.38; b. pt., 120° C.; total solids, 65%; ash, 29%; potash (K_2O), 13.4%; fats (by ether), 0.7%. The concentrated liquor readily cokes to a porous solid containing from 40 to 46% of potash as K_2O . One sample of coke produced from waste from wool scoured with naphtha contained 46.3% of potash, and its ash had the following composition: Soluble in water, 95.2%; potassium carbonate, 77.3%; equivalent K_2O , 50.0%.

The calcined coke from ordinary wool waste using soda soap (potash soaps have scarcely been obtainable since the war began) had the following composition: Soluble in water, 88.5%; silica, 3.5%; potassium carbonate, 44.9%; sodium carbonate, 40.0%.

To recover the grease, the waste, first heated to 60° C. or above, is allowed to subside for several hours in a tank, and is then reheated to 72° C. and passed through centrifugal machines, where from 40 to 70% of the ether-soluble fats are removed. The hot effluent should then pass directly to the evaporator to avoid loss of heat.

The grease from the machines contains from 5 to 20% of water and some suspended colloidal matter. It is re-emulsified and re-machined to produce a grease containing less than 2% of water and practically no suspended matter. The quality of the centrifugal grease varies greatly, depending upon the grade of wool washed and the care exercised to prevent fermentation of the waste during sedimentation and degreasing. The best grease is produced from Australian wool and the worst from the dirty Territory and domestic wools. U.S.P. lanolin can be made from the best grease, while the cheaper greases are used for stuffing leather, lubrication, veterinary ointments, etc. The grease recovered by the solvent process is dark coloured and contains many organic impurities. Its odour is pronounced and it is used chiefly for stuffing leather, for cheap lubricants, and in general for those purposes for which acid wool grease is employed.

Cost. The average wool-scouring plant probably has two trains of bowls discharging 12,000 gallons or 200,000 lb. of waste daily. The cost of a plant for the disposal of this waste will vary

greatly with conditions, but will rarely, if ever, exceed \$10,000, even at the present high prices. The 200,000 lb. of waste will, on the average, contain 4000 lb. of grease and 2500 lb. of potash, and there may be recovered therefrom 2000 lb. of centrifugal grease, 1750 lb. of extracted grease, and 1600 lb. of potash. The cost of operation is approximately as follows:—

	Per diem.
Cost of centrifugal process	\$45
Cost of evaporation	48
Cost of degreasing	35
Cost of coking	17
Management	20
Total	\$165

Value of products.

2000 lb. of centrifugal grease at 10c.	\$200
1750 lb. of extracted grease at 8c.	140
1600 lb. of potash at 17.5c.	280
Total	\$620
Daily profit	\$455

This profit may seem large, but one mill operating three trains of bowls is at present making a profit of \$500 a day on centrifugal grease alone, and it is believed that at present prices a plant may be built and amortized before the end of the war. At pre-war prices, the cost of operation would be slightly less and the value of the products \$184, thus leaving a small profit for a plant of this size. In the case of a small, single train plant, the pre-war profit would have been a nominal one but the stream would have been kept clean and valuable products would have been reclaimed from a waste otherwise a nuisance. It must be borne in mind that when potash is recovered no waste is discharged into the stream, and even the degreasing plant alone greatly improves the character of the polluted stream.

The waste has another set of possible by-products, namely, those produced by the destructive distillation of the coke—among them some valuable waxes of high melting point, and possibly other commercially valuable substances. However, these possibilities have not yet been sufficiently studied for one to give an opinion regarding their value.

This paper deals, of course, with a general problem, but just as wools vary, so do the applications of the process in specific cases. Therefore each case, beginning at the scouring room and ending at the stream into which the waste is discharged, must be studied with care before decision can be made regarding the practicability of recovering valuable by-products from the waste in question. Every plant should make this study so that the dearth of wool grease and potash, formerly imported, may be in a measure relieved.

Communications.

THE MANUFACTURE OF PORTLAND CEMENT.

BY EDWARD D. BOYER.

[ABSTRACT.]

The history of the commercialising of Portland cement is a history of inventions and improvements in its manufacture. Perhaps the greatest among these is the substitution of the rotary kiln for the old stationary dome kiln. In the early days the mixture of the raw materials, usually in the form of moulded brick, was placed in these dome kilns with alternate layers of coal or coke. The output of these kilns seldom exceeded 100 barrels per day. This process of burning was continued until about 24 years ago, when the Atlas Portland Cement Company began experimenting with and rapidly developed the rotary kiln. This type of kiln is to-day being used for calcining Portland cement

in every mill in the United States, and was rapidly adopted in Germany and England. These rotary kilns produce from 500 to 3000 barrels per day according to their size, which varies from 60 ft. long by 5 ft. diam. to 240 ft. by 12 ft., and they alone have been largely instrumental in reducing the cost of manufacture to such an extent as to make Portland cement an economical building material.

Portland cement clinker is one of the most refractory materials and the machinery used for its reduction to a fine powder—78% through a 200-mesh screen—wears out rapidly and constant repair and renewal of parts are required, making the cost of grinding very high. But undoubtedly the most serious loss is that of the heat and dust passing out of the stacks from the rotary kilns. Some few of the plants use the heat from the stacks for generating steam under their boilers, and since the outbreak of war, particular attention has been given by a number of the manufacturers to the recovery of potash from the dust of the kilns.

Portland cement consists mainly of lime and silica, with a certain amount of alumina and small amounts of free salts of potash, soda, and magnesia. The raw materials may contain as much as 2½% of potassium oxide, but normally 0.8 to 1.25%. Efforts are now being made to recover this potash, and it is claimed that a large plant in California has succeeded in doing so. Two Eastern cement plants have also adopted the system and claim success. It is estimated that the Portland cement mills of the United States as at present operated are capable of producing about 100,000 tons of potash per year, or about 33% of our normal requirement.

The process used is the Cottrell electrical precipitation method, the purpose of which is the removal of suspended particles from gases by the aid of electrical discharges. The gases carrying the suspended finely-divided particles of dust are passed between two systems of electrodes, one of which carries a negative electrical charge, while the other carries a positive charge. In ordinary practice the negative electrodes are small in size, such as iron wire or chain, and the positive electrodes are large, such as iron plates or pipes. The gases are divided into several channels and passed through the space between the wires and the plates or pipes; in the latter case each pipe has a wire placed along its longitudinal axis. The electrodes are charged by being connected with a source of high voltage electricity, consisting ordinarily of a high voltage transformer for increasing the electric potential up to the working voltage of 70,000 to 80,000 volts, a rectifier for changing alternating current into direct current, and a switchboard provided with the necessary standard control equipment. The suspended particles while passing between the electrodes become electrically charged and are then driven to the plates or the inner surface of the pipes by the forces of the electric field.

Each precipitator consists of a lower header and an upper header, with twenty vertical tubular electrodes fastened between. The lower header is connected by means of a damper inlet with the main distributing flue, and the upper header is connected with a small separate stack mounted directly over the unit, this stack also being supplied with a damper at the outlet end. The bottom of the lower header is provided with a hopper to receive the collected material, which is delivered by feed spouts to cars on the ground floor. The tubular or "collecting" electrodes are 13 inches outside diameter and 15 feet long, and consist of standard well casing. They are fastened securely to both the upper and lower headers by means of flanged ends on the pipes, these being riveted to the header plates. The inner or "dis-

charge" electrodes consist of No. 9 copper wire, this diameter wire corresponding to the conductivity of the gases here under treatment. These discharge electrodes are supported upon bus bars which, in turn, are supported upon insulators, all in accordance with standard design.

In the operation of these treaters, the finely-divided dust carried out of the kilns by the gases is precipitated upon the tubular electrodes, as the gases pass up through the precipitator. The precipitated dust clings tightly to these electrodes, which are given a mechanical jar from time to time, and the dust, thereby shaken loose from the electrodes, falls into the hoppers underneath the lower header. Each hammering member has six loosely hung hammers mounted upon it, each inner hammer serving to jar four pipes, but each pipe is hammered on two opposite sides. The hammers impinge upon lugs welded to the sides of the pipes; adjacent lugs are fastened together by means of small bolted plates. The hammering system is operated manually. This cleaning system is very effective and simple and the cleaning of the pipes of the complete installation requires but a few minutes, and is carried out about once every two hours.

The potash is volatilised in the "burning zone" of the kiln, the amount volatilised depending entirely upon the factors of time and temperature. The emission of potash apparently follows the ordinary vapour pressure laws, being quite independent of complex chemical considerations. Potash is probably volatilised from the mix in the form of oxide, which immediately reacts with various constituents in the gases to form carbonate or other salts. In the ordinary operation of cement kilns the potash combines with the sulphur dioxide, resulting from the sulphur in the fuel, and the sulphite is then oxidised immediately to potassium sulphate, which has a considerably lower vapour pressure than any of the other potassium salts which could be formed by reacting with the various constituents of the gases present in the kiln.

The resulting fume of potassium sulphate, together with the dust mechanically blown out of the kiln, is carried by the kiln gases into the electrical precipitators, in which a fractionation of the material is accomplished, as outlined above. The commercial result at the California factory has been that a material containing 10% K_2O is being collected in the two outer hoppers of each division of the main precipitator system, as well as in the multiple pipe treater, and this material has found a ready market in the fertiliser industry of California. It has served to give a profit to the California factory upon the entire precipitation plant investment. The average potash content of the raw mix is about 0.5%, and the volatilisation in the kilns, as ordinarily operated, does not exceed 60% of even this small amount of potash present. The California installation cost \$180,000 and their recoveries per day are 65 tons of dust and 20 tons of potash material (average 10% K_2O).

There are still wonderful possibilities for research in the manufacture of Portland cement, including improved grinding machinery, burning of the raw material (which perhaps some day will be done electrically), collection of dust, recovery of potash and other by-products, and the practical control and use of the waste heat from the kilns.

The powdering or pulverising of the raw materials is one of the most important steps in the manufacture of cement. Decided advances have been made in the last few years in grinding and pulverising machines, and types found to be most advantageous in the cement industry are quite novel. Grinding machines nearly all work on the principle of striking or pounding the material between a hammer in some form and a solid metal

mass. The ball mill, for example, is a horizontal iron cylinder, 6 to 8 feet in diameter and 4 to 6 feet long, revolving about its axis 23 to 25 revolutions per minute. This mill is partly filled with steel balls and is lined with steel plates fastened inside the cylinder and arranged in steps. In rolling around the balls fall from these steps on the material, which is fed in at one end, until it passes annular screens fastened to the outer side of the cylinder and revolving with it. The particles too coarse to pass the screen are returned to the grinding chamber through the openings beneath the stepped grinding plates. The output of these machines ranges from 15 to 24 barrels per hour.

Another type of grinding machine is the Griffin mill, which consists essentially of a steel ring or disk against the inside of which a heavy steel crushing roll, mounted on a pendulum suspended by a universal joint, is made to roll by centrifugal force. The pendulum is rotated by a pulley and the grinding zone is between the steel outside stationary ring and the revolving pendulum. The output of these mills is about 8 barrels of raw material per hour, to a fineness of 80% through a 200-mesh screen.

A new use for Portland cement, brought about by the war, is at present being rapidly developed with every reason for success, and that is the construction of ships and barges of concrete. Ships of this character have been successfully built recently in Norway, and a 5000-ton ship is at present being constructed in San Francisco, while on November 21st last, a 250-ton ship was successfully launched at Montreal. The American Concrete Institute and the Portland Cement Association have organized Committees which are studying the construction of vessels of this type, and these Committees have designed a reinforced concrete barge of 2000-ton carrying capacity, and have every reason to believe that it will be successful.

The author also gave a brief description of the process of manufacturing Portland cement.

DISTILLATION TEST OF PETROL.

BY N. A. ANFILOGOFF.

Distillation tests are carried out either for purposes of analysis, for trade purposes, or for manufacturing purposes.

For the purpose of purely analytical work, to enable the chemist to determine the maximum quantities existing within certain predetermined ranges of boiling temperatures, and/or to determine if the petrol consists of naturally consecutive hydrocarbons, or a mixture of volatile and heavy grades of distillate, one cannot do better than follow the methods advised by Professor S. Young, in his treatise on "Fractional distillation," and by employing one or other of Young's dephlegmator columns, accurate results can be obtained. In such analyses of petroleum spirit, I have not found it necessary to use the Young and Thomas evaporator; any of the less severe still-heads, like either the "pear" or "rod and disc" dephlegmators, was found adequate. For accurate work of this description, it would be necessary to introduce corrections of the boiling points for barometric pressure and for the length of the thermometer stem which is not covered by the vapour.

For trade purposes the distillation test is employed to denote the "trade" quality or grade of the petrol. For this purpose the Redwood test is the recognised test employed, but a number of other tests are also used, and as the multiplication of apparatus and methods leads to great confusion and disparity of results, a standard method and apparatus should be devised and employed.

From the manufacturer's point of view, to enable him to decide what grade of petrol and what quantities he can obtain from the crude material, any method would serve, as long as there is some known relation between the apparatus and test employed in his laboratory, and the maximum efficiency of his large scale plant on the works.

It is obvious that the most rational method of testing the petrol for both trade and manufacturing purposes, would be the one which most nearly approaches the best method employed by the analytical chemist, and which would, at a glance, give both the manufacturer and the merchant or the consumer a comprehensive idea of how much distillate it will yield below certain defined temperatures of boiling. Such a method I claim mine to be.

During the years 1902, 1903, and 1904, when petrol commenced to be imported in bulk and the motor industry was being developed at a very rapid rate, heavier grades of petrol were gradually introduced on the market to replace the quondam "680" spirit, which was the only grade supplied for internal combustion engines. Being at that time chemist in charge of the only refinery in this country distilling petrol from crude oil, and being also connected with the landing station where the whole of the petrol destined for this country was landed, I modified the Redwood method of testing to enable the distillation to be carried through more quickly; notwithstanding the fact that my method of testing only took some twenty minutes as against forty to fifty minutes by the Redwood method, the results agreed practically within the limit of experimental error.

At that time the Sumatra spirit, with a sp. gr. of 0.702 yielded some 80% boiling below 100° C., the Rumanian imported spirit with a sp. gr. of 0.700 yielded about 85% boiling below 100°, with a "final boiling" point of 135°, and the Rumanian spirit manufactured at Thames Haven, with a sp. gr. of 0.712, was put on the market to compete with imported lighter grades having 70% boiling below 100° C., with a final boiling point of 145°. Within the years mentioned even the very heavy Borneo spirit imported, having a sp. gr. of 0.774, yielded about 45% boiling below 100°, and had a final boiling point of 165° C. The initial boiling point was not insisted on in years gone by.

The results obtained by my method only commenced to disagree slightly with those of the Redwood method when heavier grades had been introduced and spirit was put on the market which contained less than 20% distilling below 100°, and I maintain that this is due to the initial position of the Redwood thermometer for ascertaining the initial boiling point, which causes, in that method, masking of the presence of the lighter hydrocarbons.

A glance at the appended table will show that, except for the initial boiling point and the percentages below 100°, our tests agree, and where the percentages yielded by the petrol below 100° are more than 15%, the percentages at the trade-temperature requirement of 100° and over, agree with those indicated by Redwood's test.

The method described below has been employed consistently at Thames Haven, during the past 15 or 16 years, and has proved particularly advantageous since 1908, when the Thames Haven Petrol Distillery was installed. At this distillery to-day nearly 2,000,000 gallons are distilled per week, and not infrequently 30 or 40 control tests have to be carried out in a day.

My method of testing consists in the use of the regulation Engler flask of 150 c.c. capacity in which 100 c.c. is distilled. The condenser employed is a 24-inch glass tube with an 18-inch wafer jacket over it, the inner tube preferably being straight, without an enlarged inlet, so as to

avoid having the small pocket of liquid where the narrow tube is sealed on to the short wider tube. I have found a condenser of this length desirable, as though the vapour will be condensed in a shorter condenser, it does not always follow that it will become cooled to room temperature. The thermometer, which is preferably not calibrated for the first four inches above the mercury bulb, is placed in such a position that the top of the mercury bulb is half an inch below the outlet of the side tube. The fact that the calibration does not start at the commencement of the mercury column, obviates the reading of temperatures inside the cork, and therefore obviates moving the thermometer up and down. The moving of the thermometer down nearer the boiling liquid during the progress of the distillation, exposes a certain amount of unheated thermometer stem, on which the vapours condense, lowering the temperature immediately.

When the distillation flask and condenser are connected in the usual way, and the thermometer is placed in the position specified, the flask is heated by the Bunsen burner and the initial boiling point noted as the temperature at which the first drop falls from the thermometer back into the flask due to condensation of vapour. Distillation then continues uninterruptedly at the rate of two drops per second till the bottom of the flask is dry. In this way the whole distillation only occupies 20 minutes, and the position of my thermometer prevents the masking of the presence of lighter hydrocarbons, which undoubtedly happens in the Redwood method.

A slow rate of distillation, as specified in the Redwood method, must obviously give incorrect results when the petrol to be distilled either contains hydrocarbons of very low boiling point or is a mixture of petrol and condensed casing-head gas, which has a notoriously low boiling point. In such a case a considerable percentage of the condensed vapour will evaporate from the receiving measuring cylinder and will therefore give inaccurate readings. It is, of course, impracticable to enclose the receiving cylinder in an ice-chest, to prevent evaporation, as in that case, too, the reading will be inaccurate, since the distillate should be at the same temperature as the liquid before it was placed in the still for testing.

My method thus differs from the Redwood specification, firstly in the initial boiling point, and secondly in the speed of distillation. It is very difficult to define the initial boiling point of a petrol, seeing that the liquid consists of a series

of hydrocarbons of different boiling points, but if the boiling point of a liquid is identical with the condensing point of its vapour, under the same pressure, the initial boiling point of such a liquid as petrol should be the temperature at which the first vapours given off are condensed. It would be impossible to observe this point with the Redwood method where the thermometer is immersed in the boiling liquid, and is only raised to its vapour position with the ascending vapours, in which short time the thermometer has no opportunity to cool sufficiently to register the condensing point of the first vapours passing over.

It is to be noted that, with the exception of the position of the thermometer, the method devised by Ubbelohde and Holde resembles my method and has been adopted by the Deutsche Verband für die Materialprüfung der Technik, for all trade, technical, and customs purposes. In their case the thermometer is placed in such a position that the top of the mercury bulb is just below the side outlet of the Engler flask, and their initial boiling point is the temperature registered by the thermometer when the first drop falls from the tail-end of the condenser. I do not agree with their position of the thermometer, because the slightest variation in the flame, or the slightest draught on the flask, will create a slight vacuum, and the cold air drawn in from the condenser is bound to affect the thermometer readings. This is not so marked in my method, because of the position of the mercury bulb below the outlet. I also do not agree that their initial boiling point temperature is the correct one, because by the time the first drop of condensed liquids falls from the tail-end of the condenser a considerable amount of further vapour has entered the condenser, and the temperature registered is that of the then ascending vapour and not of the vapour which had already condensed.

My method of testing the boiling points of petrol by distillation, like the Redwood method, is quite simple, and requires no special apparatus, and, with a little practice, any intelligent person can get concordant results.

One other claim my method has for consideration by the petroleum trade as a whole is that, except for the very lightest hydrocarbons, results obtained by it are not very divergent from distillation results obtained by the use of an "eight-pear Young's still-head," and also I have habitually controlled my stills, and was able at the refinery to obtain products at least in the same percentages as those indicated in my preliminary distillation.

Comparative tests of various trade grades of petrol.

MODERN PRACTICES IN COAL TAR DISTILLATION.

BY T. HOWARD BUTLER, PH.D., M.S.C.

(Abstract.)

The composition of coal tar is so varied that it is impossible to give any general analysis that would be representative; it is dependent on such factors as temperature of carbonisation of the coal, nature of coal used, the shape of retorts, etc. Generally speaking these factors combine together to form a tar that contains a preponderance of paraffins with a low percentage of pitch, or one that contains nearly all ring compounds with a higher amount of pitch and free carbon. At any rate, tar can be looked upon as a very complex mixture, having a sp. gr. of approximately 1.1 to 1.2.

The apparatus used for the distillation of tar varies amongst different distillers, but practically only in detail, such as, size, type of still, materials used in construction, etc. Generally speaking, the still is of a vertical type having a dish bottom, which insures longer life and greater heating surface. The stills are as a rule arranged in a row and are generally of 10—20 tons capacity.

The modern practice in economising heat in distillation is to attach to the still a pre-heater, in which the vapours from the still are condensed by raw tar, which is afterwards used as the still charge on the next time of working.

Many forms of continuous stills have been tried, but have so far not been very freely adopted for the distillation of tar, except in cases where only dehydration of tar is required. One might mention such plants as Hird's, Wilton's, and Lennard's stills, the latter being interesting in so far that it is worked on the principle of fractional condensation and not fractional distillation.

The fractions obtained from the distillation of coal tar are by no means constant, as they depend upon the plant used, and the plant available for working up the products produced.

For the sake of these remarks the fractions may be divided up as follows:—

- | | |
|--|--------------|
| (1) Ammonia liquor that distils approximately up to | 150° C. |
| (2) Light oil that distils approximately at | 150°—220° C. |
| (3) Creosote oil that distils approximately at | 220°—280° C. |
| (4) Anthracene or yellow oil that distils approximately at | 280°—350° C. |
| (5) Pitch. | |

Pitch from the still at the end of distillation is run into coolers, where it is allowed to remain until cool enough to run into bays or beds. The handling of pitch is a problem of great importance to the tar distiller, as, being approximately 60% of the crude material, the quantity is large; also the danger to workmen in working it is great, the dust therefrom causing temporary blindness. Again men working in contact with pitch for some years have a tendency to a terrible disease known as "pitch cancer."

One of the most successful modern methods of dealing with pitch, is to run it while hot into pans holding about $\frac{1}{2}$ ton. The pitch is allowed to cool, after which the pans are swung over a railway truck by means of a crane and tipped, the whole block of pitch falling into the truck. By this method the pitch is not handled by men at all; the only objection being a large capital outlay required in pans, light railways, cranes, etc.

Anthracene oil is allowed to cool in boilers having some form of slow agitation, when anthracene is deposited. This is filter-pressed, passed through a centrifugal machine, or hot-pressed, when a dark green powder containing about 40% of anthracene is obtained. This can be further purified by means of various solvents, one of the most valuable being pyridine. The purified anthracene finds a valuable use at the present day as the parent substance of alizarin dyes.

Creosote oil on being cooled deposits naphthalene in a crystalline form, and on being drained off is ready for the market for use as wood preservative, liquid fuel, etc. The naphthalene so obtained is drained or centrifuged. This product can be purified by washing while melted with sulphuric acid and caustic soda, and is then either sublimed or re-distilled and crystallised.

Light oil. This fraction is in many ways the most interesting, especially at the present day, as it contains the tar acids, the most important of which is phenol, from which are prepared picric acid and all the other explosive picrates. Also in this fraction is found benzene, from which synthetic phenol is prepared, and toluene, which is nitrated to the familiar trinitrotoluene (T.N.T.).

It is first necessary to extract from the light oil the tar acids, and the process most freely adopted is the one known as the CO_2 process. In this the light oils are washed with caustic soda, and the sodium salts of the tar acids are admitted to a cylinder through which carbon dioxide is passed. On being neutralised the free tar acids float to the top, and the resulting sodium carbonate is used for manufacturing a further quantity of caustic soda, by boiling with the lime obtained from a lime kiln, which supplies the carbon dioxide. This process, which works in a cycle, is very efficient and the loss in working is not high. The acid-free light oil is then submitted to washing with concentrated sulphuric acid and caustic soda, and on fractional distillation benzene, toluene, xylene, and heavy naphtha are obtained.

The uses of the various products obtained from the distillation of coal tar were mentioned. Also some of the effects brought about in the industry through War conditions were discussed.

ANTISEPTICS.

A SHORT ACCOUNT OF WORK DONE FOR THE MEDICAL RESEARCH COMMITTEE IN THE PATHOLOGICAL DEPARTMENT, EDINBURGH UNIVERSITY.

BY THEODORE RETTIE, D.S.C.

In January, 1915, the National Insurance Medical Research Committee, at the request of the War Office, issued an appeal to the various medical schools to institute research on several problems which had been encountered in the medical service at the Front. One of the most urgent requirements was a reliable antiseptic for the treatment of heavily-infected wounds, with special

attention to spore-bearing organisms. Professors Lorrain Smith and Ritchie at once organised several sets of workers to investigate the various problems, under their own direction. The work on antiseptics was carried out by the Professors, Dr. A. Murray Drennan, now Professor of Clinical Pathology in Otago, Dr. W. Campbell, now a Captain in the R.A.M.C., stationed at Alexandria, and myself.¹

It may seem strange that over 40 years after the introduction of antiseptic surgery by Sir Joseph Lister no ideal antiseptic has been devised for such emergency treatment: the explanation, I think, is to be found in the tendency of modern surgery to leave as much to the recuperative power of the patient's own body as possible. In preparing for operation the surroundings of the patient are rendered as sterile as possible. Instruments, swabs, dressings, everything that will come in contact with him, are sterilised by heat, in fact nothing that is not sterile is allowed to touch him. Under such conditions the only antiseptic necessary is some iodine solution to sterilise the patient's skin, and lysol or such preparation in which to place instruments after use. In accident cases where the wound is already infected, the injured tissues are carefully dissected out under chloroform and the wound cleansed with some strong antiseptic, most often with 5% aqueous carbolic acid, Lister's original antiseptic, or, by some of the ultra-septic surgeons, with large douches of sterile saline (0.85% salt solution—this is known as normal saline as its osmotic pressure is equal to the pressure of the plasma of the body). Such procedure, though successful with a limited number of patients, obviously cannot be applied in a casualty dressing station; the wounds are always contaminated: they are deep, often ramifying, and may contain pieces of clothing or splinters, all presumably carrying infection. To meet such conditions powerful remedies are necessary, but they must be discriminatingly powerful; microbes which are vegetable cells must be killed, both vegetative forms and spores, which are much more resistant. At the same time the animal cells of the tissues must be damaged as little as possible by the antiseptic; free drainage for all discharges from the wound must also be maintained.

In opposition to the antiseptic method there is what has been called the physiological method of wound treatment, introduced by Sir Almroth Wright. The wound is treated with a hypertonic saline solution, i.e., a solution having an osmotic pressure higher than that of the plasma. As a result of this, fluid is rapidly poured out by the tissues, the idea being that the microbes are thus washed out of the wound and at the same time destroyed by the bactericidal properties of the lymph.

In support of this method the argument was advanced that any antiseptic damages the tissue to which it is applied to such an extent that the value of it as a destroyer of bacteria is lost, and the dead cells and coagulated albumin which the antiseptic leaves in the wound are a fertile source of further trouble. By hypertonic saline treatment this difficulty is avoided. With these two principles in mind, our object was to find an antiseptic agent thoroughly efficient as a killer of bacteria and spores, and at the same time harmless from the point of view of the wound tissues.

Our first step was to test the comparative efficiency of all the antiseptics in general use. It is obvious that it is impossible to make a definite statement as to the value of an antiseptic for wound treatment from its behaviour under laboratory conditions. Most elaborate experimental methods have been devised in the endeavour to fix a standard by which antiseptics may be tested,

but further research has shown that so many factors enter into the efficiency problem that test tube methods have come to be regarded more or less as a compromise. For instance Chick and Martin² have shown that what might be called mass action, i.e., the actual number of bacteria exposed to the action of the antiseptic in the test tube, has a very important bearing on the efficiency. The presence of organic matter other than the bacteria has naturally a protective action in favour of the bacteria: various mixtures of bacteria with blood serum, whole blood, pus, muscle extract, etc., have been employed to reproduce as far as possible conditions likely to be met with in a wound. For our tests we decided to use pieces of heavily-infected tissues which were exposed for definite periods to a large volume of the antiseptic solution. The tissue after treatment was washed free of the antiseptic with successive quantities of sterile water, and in cases where it was deemed necessary, any residual antiseptic was neutralised by appropriate chemical methods. The tissue was then put into a tube of sterile broth and incubated: readings were taken at 24, 48, and 72 hours.

The antiseptics tested were those in use at the military hospitals in Edinburgh and others which have been more or less in general use: they were phenol, acrosyl, kymol, chinolol (oxyquinoline potassium sulphate), hydrogen peroxide, mercuric iodide, tincture of iodine, potassium permanganate 4%, methylated spirit, turpentine, salicylic acid, sodium salicylate, methyl salicylate (oil of wintergreen), glycerin, bleaching powder, bleaching powder and hydrogen peroxide (for nascent oxygen), eau de Javelle, boric acid. Our test proved very drastic: of the above only bleaching powder, 10% solution, eau de Javelle (10% sodium hypochlorite), 5% phenol, and the mixture of bleaching powder and hydrogen peroxide had any effect in delaying or inhibiting growth, and the first two were decidedly ahead of the others. The hypochlorites were thus proved, as has often happened before, to be the strongest antiseptics in general use. There are other points decidedly in their favour. Bleaching powder is cheap, easily procured anywhere, and above all it cannot be classed as a dangerous poison. On the other hand pure *Liquor calcis chlorinata* and eau de Javelle are very drastic remedies and on account of their strong alkalinity and high chlorine content (about 3% available chlorine) the tissues will not stand their continued application: for this reason they have never come into general use, though they have both been used with great success on occasion. For instance in 1846 Semelweis, an Austrian physician, stamped out an epidemic of sepsis in his hospital in Vienna by using bleaching powder. Pasteur used *Liquor calcis chlorinata*, and I am informed by Sir James Russell that when he was a medical student in this University Professor Spence constantly used it. Our problem thus reduced itself to getting bleaching powder into a solution or powder that could be applied to open wounds without damaging the tissues unduly.

Following our original method, i.e., with infected tissues, and using mixtures of varying proportions of boric acid and bleaching powder with small quantities of water, we found that with equal quantities of each we got a most pungent smelling paste which had no difficulty in sterilising the tissue and on the other hand, apart from bleaching, did not seem to damage it as much as was expected. We also found that the gas (hypochlorous acid) given off by this mixture was capable of sterilising highly infected tissue, provided it was allowed to act long enough: in some of the experiments two hours was sufficient. This mixture therefore gave promise of high value as a wound dressing, and I shall have occasion to refer to it later. Solutions

prepared from this mixture were next tested and very interesting results were brought out; the bactericidal efficiency of the solution was greatly increased; instead of 3.5% available chlorine, as in *Liquor calcis chlorinæ*, one-tenth of that amount gave very satisfactory results, the free hypochlorous acid proving a much better germicide than the calcium salt.

Further test experiments were carried out with anthrax spores, one of the most virulent and resistant of pathogenic organisms; we were gratified to find that our solution in a strength of 0.35% available chlorine killed the spores in one minute.

Turning next to the action on living tissues, working first on rabbits, then on ourselves, then on patients in local hospitals, we were soon convinced that hypochlorous acid in a solution such as ours could be applied to tissues in a strength hitherto unsuspected. Large quantities of the solution can be applied to extensive wound surfaces, and may be freely introduced into the peritoneum or pleural cavity without producing any toxic effect; indeed the mixed powders may be introduced into wounds and even into the peritoneal cavity without damaging the tissues; such treatment has been found very effective in grossly infected wounds.

Pure hypochlorous acid in aqueous solution always contains free hydrochloric and chloric acids due to spontaneous decomposition, one molecule of hypochlorous acid being oxidised to chloric acid at the expense of other two molecules which are reduced to hydrochloric acid. Both are very strong acids and therefore pure hypochlorous acid is not suitable for wound treatment.

By adding boric acid to chloride of lime in the proportions above stated we have produced a solution containing calcium baborate, an acid salt of extremely low hydrogen ion concentration; on mixing such a solution with one containing hydrochloric acid, the acidity is reduced as the free H^+ ions are taken up by the boric ions forming H_3BO_3 ; the acidity of the solution therefore cannot rise above the dissociation constant for boric acid, which is very low.

By this adjustment various advantages have been secured: the alkalinity of the chloride of lime has been reduced, the full effect of the free hypochlorous acid has been secured, and the solution cannot become unduly acid. In virtue of this balance it follows that the solution can be applied freely to the tissues of the body, and that a considerable quantity can be injected into the circulating blood without harmful effect.

The high germicidal value of pure hypochlorous acid solutions was demonstrated in 1903 by Andrews and Orton.³ In test-tube experiments they found that very weak solutions of hypochlorous acid, 1 part in 100,000, would kill pathogenic organisms in one minute, but when applied to solutions containing organic matter as well as bacteria they found the hypochlorous acid so rapidly destroyed that they did not evolve any method of applying the solution as a practical antiseptic.

Putting all the above observations together we fixed on the following as safe antiseptics:—

The powder, equal weights of chloride of lime and boric acid. The solution, prepared by shaking up 25 grms. of the above mixture in one litre of water and filtering off the sediment; this solution contains about 0.26% hypochlorous acid. The powder we named Eupad and the solution Eusol—words derived from the initial letters of Edinburgh University Pathology Department.

A simple and convenient method of preparing small quantities of Eusol is to make it up from *Liquor calcis chlorinæ*, that is 10% chloride of lime; this solution, contrary to the statement in the Pharmacopœia, keeps very well if stored in a

cool dark cupboard. I have kept it for months in the laboratory with a very small loss of chlorine. This solution may be made in quantity, say two litres, filtered clear, and the chlorine content determined; the amount necessary for one litre of Eusol is easily calculated; with a good chloride of lime this should be about 125 c.c., which is diluted to one litre, and shaken with 10 grms. of boric acid; the solution remains clear.

For testing we recommend N/10 sodium arsenite solution; this solution keeps better than sodium thiosulphate; it is also better for testing bleaching powder, as chlorates do not interfere with the result, as they do in the hydrochloric acid and potassium iodide method.

Another hypochlorite solution has also been introduced as an antiseptic. It is known as Dakin's^{4,7} solution and contains sodium hypochlorite and sodium bicarbonate; its action is much the same as that of Eusol but it is decidedly alkaline.

As Eusol is a most powerful oxidising agent it is evident that its value as an antiseptic will soon be reduced in contact with organic fluids such as are encountered in an open wound; therefore in order to bring any effective solution into contact with the organisms hidden in the depths of the wound, large quantities must be used and the solution got down to the lowest recesses and pockets. To accomplish this, surgeons have various appliances with rubber tubes branching from a common source of supply; this method was applied most successfully with Eusol by Captain Miles⁵ in Edinburgh and also by Captain John Fraser⁶ in France. A similar method has been advocated by Carrel, who worked with Dakin's solution at Compiègne, and constitutes the Carrel-Dakin⁷ method of wound treatment.

We have further observed in open wounds a distinct outpouring of lymph on the application of Eusol, thus combining the advantages of the hypertonic saline treatment with the killing power of the hypochlorous acid; here also the non-toxicity of the solution tells strongly in its favour; there are no toxic by-products at all. Carbolic acid is an excellent antiseptic, but if applied to a wound in unlimited quantity it very soon produces necrosis and may even produce symptoms of general poisoning. The cresols and emulsions containing them precipitate a sticky film of resinous matter in the wound, clogging it and preventing free drainage.

In the course of our preliminary experiments on the effect of Eusol on live tissues we found that large quantities, as much as 40 to 50 c.c., could be injected into the blood stream of rabbits without injuring the animal; following up this line of investigation, with a view to attacking sepsis in the blood, we have met with a considerable measure of success. We applied this method of treatment in the first instance to a case of puerperal septicaemia in the Maternity Hospital in this city.⁸ The patient was suffering from an extremely grave form of blood poisoning; the treatment was completely successful.

Following on this, Captain John Fraser, R.A.M.C.,⁹ applied the same treatment to soldiers suffering from the acute toxæmia arising from wounds infected with the gas-producing organisms—*Bacillus Welchii*, *B. sporogenes*, etc. These organisms, which cause what is known as gas gangrene, owing to the fact that they produce large quantities of gas inside the tissues, are the scourge of the casualty clearing stations; they are spore-bearers and therefore difficult to kill and the spores are present everywhere.

In certain types of gas gangrene toxæmia, Captain Fraser found intravenous Eusol as strikingly successful as in our first case, but in others it did not seem to have any effect; and this has been the experience of all workers who have

employed the method. Sir Herbert Waterhouse¹⁰ in his report from Anglo-Russian Hospitals, says: "We entertain the highest opinion of its value as a life-saving method in many apparently hopeless cases of septicæmia and pyæmia." This treatment was the subject of much investigation under our own care at the Sick Children's Hospital in Edinburgh. A paper on the subject was published in the "Edinburgh Medical Journal"¹¹ this summer. As a result, we found that evidence of benefit was recorded in cases of lung infection, such as broncho-pneumonia, empyema, abscess of lung; in toxæmia from appendicitis, and in one case of toxic diarrhoea, also in cases of chronic meningitis. No benefit accrued in cases of rheumatism or in tuberculosis.

The problem we are now engaged on is to find out why in certain bacterial infections we can help the recuperative powers of the body and in others we cannot. We may be acting on a toxin produced by the bacteria and circulating in the blood, or we may destroy some toxic agent formed by the blood itself, or may merely stimulate a protective reaction in the body fluids. Many theories have been advanced as to the conditions found in acute toxæmia. A toxin of protein origin has been held accountable. Again, an increase in the acidity of the blood, due to the production of butyric and kindred acids by the bacteria. A later suggestion by Wright is that the antitryptic power of the blood is reduced; this allows the trypsin to prepare a suitable medium for the growth of the bacteria in the blood itself and the patient is overwhelmed by an acute invasion of the actual organisms. The subject is much too large to enter into in a paper like this. I merely indicate it to show the sort of problems that the chemist is asked to solve in pathological or physiological chemistry.

Take the question of toxins. In a rabbit of 2 kilos, weight there is, say, 100 c.c. of blood. Such a rabbit can stand without inconvenience, say, for a very safe estimate, 20 c.c. Eusol intravenously; this contains 0.05 gm. HClO; obviously 0.05 gm. of hypochlorous acid in 100 c.c. of blood can have no possible action as a direct antiseptic. On the other hand, ricin, a vegetable protein poison extracted from castor oil beans, very closely resembling the bacterial toxins, when administered intravenously to a 2-kilogram rabbit in a dose of 0.001 mgrm., kills the animal. A very small amount of hypochlorous acid would suffice to neutralise this dose, if it could reach it.

Hitherto the treatment of conditions due to organic toxins has been based on the conception of a specific antidote; for example, take diphtheria. The method of treating the disease is to inject into the patient the serum of an animal which has been rendered highly immune to the diphtheria toxin. This serum has the power of neutralising the toxin, but it is a specific power; it cannot neutralise the toxin produced by other organisms, e.g., tetanus. The interest of the method of treatment by intravenous injection of hypochlorous acid lies in the fact that we are able to introduce into the blood a considerable quantity of a strong chemical reagent which will act in a general and not a specific manner.

The chemical reaction between hypochlorous acid and blood is naturally very complex. When hypochlorous acid or hypochlorites act on proteins, the first products are chloramines. In these compounds, which have been studied by Chataway, Langheld, and later by Dakin, chlorine displaces the hydrogen attached to the nitrogen, giving compounds containing the group NCl. These substances give the reactions for free chlorine and are themselves antiseptics of considerable value. As they are formed in the wound or in the blood stream in intravenous injection, and may continue to exist as such for some time,

they may prove to have an important bearing on the reactions of the body. They ultimately break down to aldehydes, nitriles, carbon dioxide, ammonia, etc. Work on these compounds as antiseptics has been carried out by H. D. Dakin¹² and others working in Professor Cohen's laboratory at Leeds, and two chloramine antiseptics have been prepared and are now in extensive use. They are known as chloramine T, which is *p*-toluene sodium sulphochloramide, $\text{CH}_3\text{C}_6\text{H}_4\text{SO}_2\text{NaCl}$, and dichloramine T, toluene-*p*-sulphodichloramine, $\text{CH}_3\text{C}_6\text{H}_4\text{SO}_2\text{NCl}_2$. The former is soluble in water and is used in a strength of 0.5%. The dichloramine is insoluble but dissolves in eucalyptol, which is then diluted with paraffin oil.

In the exigencies of war surgery a large variety of antiseptics, including several synthetic dyes, have been tested, but the general conclusion seems to be that hypochlorous acid, one of the oldest antiseptics, still remains the most reliable for general wound treatment.

In Eusol the full value of hypochlorous acid is available without the drawbacks inherent in the earlier solutions containing this potent reagent.

DR. CHARLES A. KEANE IN THE CHAIR.

THE TOXICITY OF METHYL ALCOHOL IN RELATION TO ITS INDUSTRIAL USES: A REVIEW OF THE PUBLISHED DATA.

BY THOMAS D. MORSON.

Introduction.

In the course of an investigation into the question of the use of methyl alcohol and methylating agents generally for various industrial purposes, the author found it necessary to have a complete search of the literature carried out. It soon became evident that a mass of information was available as to the toxic effects of methyl alcohol. The references are distributed through a wide range of scientific publications, and these have been tabulated and in some cases extracted. The value of the compilation will be appreciated mostly by those who have previously attempted to supply evidence that methyl alcohol is a poison. The work has been carried out with a definite object, concerning which it is sufficient to say here that pure methyl alcohol is classified by the Customs and Excise authorities as "plain spirits" and has been subjected to the same rates of duty as pure ethyl alcohol.

The origin of the classification of pure methyl alcohol as "plain spirits" is not clear, but it doubtless arose from the assumption that this article was or might be regarded as potable and capable of substitution for purposes for which

pure ethyl alcohol was used. It is reasonable to suppose that if it can be proved definitely that this "plain spirit" is highly toxic the main argument for taxation on the grounds of potability falls to the ground. If, in addition, it can be shown that pure methyl alcohol is the starting point for many manufactures of the greatest national importance, one may hope that unnecessary restrictions will no longer be allowed to stand in the way of the development of British chemical industry.

These are the broad lines upon which action may be taken. I have only to add that to-day British chemical manufacturers, who are interested in this question, are both united and determined. Restrictions which have proved an unfair and unjustifiable burden on the British manufacturer, must be removed, or modified, to enable us to compete successfully with foreign rivals in the great industrial struggle that lies before us.

Production of methyl alcohol.

Supplies of methyl alcohol before the war were obtained from the United States, Canada, and France, but chiefly from Germany and Austria. It is obviously desirable that the British Empire should be self-supporting in this respect. The following are the views of a prominent British wood-distiller:—

"Before British chemical manufacturers can hope to compete successfully with the foreigner in the manufacture of dyes and fine chemicals used in the arts and for medicinal purposes, it is essential that they be able not only to produce these substances cheaply and in a high state of purity, but also that they should be independent of the foreign manufacturer for the chemicals required in their production—otherwise it will be in the power of the foreign manufacturer to limit the extent of the expansion of the British industry. In this connection, the products of wood-distillation are second only in importance to the products of what might be termed the sister industry—coal tar distillation.

"There is immediate necessity for encouraging the expansion of the wood-distillation industry, the present decadent condition of which is due largely to the fact that wood distillers, unlike their foreign competitors, could find no market for their methyl alcohol owing to the heavy restrictions imposed upon it by the Government. These restrictions not only hinder the expansion of the wood-distillation industry by, and to, the limited demand for wood spirit as such, for denaturing purposes and varnish making, but also the greater industry of dyes and fine chemicals, upon which the wood-distillation industry depends for an outlet for its products. The result is that methyl alcohol (pure) is not produced in this country to any extent—if at all—while of the other necessary products of wood distillation only a mere fraction of this country's pre-war requirements of acetone, acetic acid, and the acetates, was produced at home."

Another manufacturer makes what is, in my opinion, a very valuable suggestion. He proposes to replace the denaturant of "methylated" and "industrial" alcohol by a cheaper and equally efficacious substance. By so doing, the whole of the crude methyl alcohol produced in this country could be rectified to pure methyl alcohol for essential industrial purposes.

The importance of conserving supplies of methyl alcohol cannot be over-stated. To-day it is little short of criminal folly to waste (I use the word deliberately) wood alcohol for denaturing purposes.

The importance of pure methyl alcohol in industry.

In support of the claim that methyl alcohol is,

in effect, a "key" chemical, it will suffice to give a very brief survey of its main uses. In this connection I have to acknowledge with grateful thanks the assistance of a number of my fellow-manufacturers, who have sent me useful information and practicable suggestions. Much information is available from the Minutes of Evidence taken before the Departmental Committee on Industrial Alcohol and still more from the papers by T. Tyrer read before this Society in March, 1903, and March, 1904.

The position has materially altered since then owing to the outbreak of War, and it is mainly from this point that I review the question under the above heading.

Industrial uses of methyl alcohol (pure).

In further support of the claim that methyl alcohol must be regarded as a "key" chemical it will suffice to summarise as follows:—

Manufacture of dyestuffs.—Methyl alcohol (pure) is absolutely essential for the production of a vast range of dyes containing methyl groups, and is necessary also as a solvent.

Dyestuffs and intermediate products can be imported into Great Britain free of duty and the methyl alcohol which they contain (as methyl groups) pays no tax.

Manufacture of medicinal chemicals.—The necessity for using a methyl alcohol as pure as possible in this class of manufacture is vital both from the therapeutic and economic standpoint. The purposes for which it can be used may be divided into:—

(1) Where the alcohol is essential for the process in question.

(2) Where it possesses advantages over industrial methylated spirits or other duty-free solvents.

The replacement of hydrogen atoms by methyl groups, which is an essential feature of the preparation of a number of drugs and fine chemicals, usually necessitates the use of the methyl ester of an inorganic acid. In the preparation of methyl salicylate, for example, the methyl alcohol and salicylic acid are made to react in presence of a mineral acid and, whilst absolute purity of the methyl alcohol is not essential, the purer the alcohol employed the less trouble will be experienced in the purification of the final product. In cases where a hydroxyl group has to be converted into a methoxyl group, or methyl added to tertiary nitrogen (as in the preparation of phenazone) the use of a methyl ester of a strong (generally mineral) acid is unavoidable. For purposes of this character the following methyl esters are available:—Chloride, bromide, iodide, nitrate, toluene, sulphonates, picrate, sulphate, and occasionally ester-salts such as sodium methyl-sulphate.

In preparing any of these compounds impurities in the methyl alcohol are disadvantageous but do not greatly hinder the preparation of the chloride, bromide, or iodide. These three compounds are, however, of little use for other reasons.

The most convenient methylating agent known is methyl sulphate. Its great reactivity and high boiling point (188° C.) generally render the use of autoclaves unnecessary. In the preparation of methyl sulphate, methylsulphuric acid is first produced and subjected to distillation. Unless methyl alcohol of high purity is employed, the methylsulphuric acid is dark in colour, contains tarry substances, and chars badly on distillation. Both the yield and purity of the methyl sulphate are affected adversely, and whilst a certain amount of the impurity can be removed by distillation, complete removal of the condensation products derived from the impurities in the methyl alcohol is almost impossible. In the case of salts of methylsulphuric acid, unless pure

methyl alcohol is used the impurities cling to the salts and their purification by repeated crystallisation is impracticable owing to the ease with which they decompose in solution. The use of impure methyl alcohol in preparing methyl sulphate or its salts is very wasteful.

The manufacture of many medicinal chemicals in this country is dependent on the use of pure methyl alcohol free from revenue restrictions.

Manufacture of formaldehyde and its derivatives.—Formaldehyde forms the starting point of a number of syntheses. The products are largely used in medicine (e.g., hexamine) and the arts (e.g., synthetic resins). The manufacture must be carried out with pure methyl alcohol.

Manufacture of photographic chemicals.—Only pure methyl alcohol is suitable for this class of preparation. Previous to the war large quantities of these were made in Germany and at such prices that it could only have been possible with unrestricted duty-free methyl alcohol. It will be necessary that the use of pure methyl alcohol, duty free, shall be made easy, subject to certain unhampering conditions of liability and returns as to manufacture, if these photographic chemicals are to be produced in this country in quantity and at a price to compete with the German productions.

The foregoing statements will have sufficed to emphasise two facts:—(1) The importance of pure methyl alcohol in chemical industry. (2) The economic difficulties which hinder the development of manufactures requiring its use.

Before passing to the main heading of this paper I would like to quote the following extract from the Report of the Departmental Committee on Industrial Alcohol (1905):—

"Methyl alcohol does not fall within the charge to spirit duty in Germany and may be used freely for industrial purposes without control by the revenue authorities."

The toxicity of methyl alcohol.

So far as I am aware the toxicity of methyl alcohol has remained up to the present a disputed question in this country.

In addition to searching the literature I have endeavoured to obtain first-hand evidence from cases actually occurring here. Owing to the comparatively restricted use of pure methyl alcohol in this country, for reasons already referred to, experiences are not easily obtainable. One manufacturer, however, reports as follows:—

"I have never experimented with it personally and do not intend to do so, as I have been aware of its deadly poisonous action from experiences gained in foreign aniline colour works years ago, where workmen, known dipsomaniacs, have taken it as a potable spirit with deplorable results, when taken in only minute quantities. I have, however, had experiences in my own works of the influence of its vapours and have found a complete derangement of the mental faculties, together with a loss of vision, which, I believe, would have produced a state of coma if the surrounding conditions had been prolonged. Some of my workmen suffered in a similar manner, some more acutely than others, dependent, no doubt, upon the density of the vapours. But all were affected similarly."

"For a concrete case of poisoning which occurred at the Docks of the Manchester Ship Canal last year, when three men lost their lives through taking some methyl alcohol drained from empty drums and adding same to their tea, I must refer you to the report of the inquest before the Salford Coroner. The evidence was conclusive enough and corroboration can be found in foreign publications dealing exhaustively with the impossibility of regarding methyl alcohol otherwise than as a deadly poison."

In America the poisonous properties of methyl alcohol have been very thoroughly investigated. The results are collected in a pamphlet entitled "Blindness from Wood Alcohol," by Dr. Casey A. Wood, published in 1914 by the American Medical Association. The conclusions arrived at may be summarised to this, that methyl alcohol is a deadly poison and it should only be available to the general public under the restrictions usually applied to poisonous substances. The report is so complete and probably so little known in this country that I may be pardoned for quoting extracts somewhat extensively.

"In the years 1903—1904 the late Dr. Frank Buller of Montreal and myself set about collecting the histories of cases of poisoning to that date. Doubtless many instances of wood-alcohol poisoning escaped this inquiry, but we found and reported 275 instances of death or blindness (sometimes both) directly traceable to drinking, or inhaling the fumes of "Columbian Spirits" or some other form of "deodorized" wood alcohol. At that time we drew the following conclusions:—

1. Methyl or wood alcohol, in any of its forms, and all methylated preparations as well, are dangerous poisons, menacing both life and eyesight.

2. It is used as an adulterant of, and substitute for, grain alcohol in cheap whisky and other alcoholic beverages, not to mention Jamaica ginger, lemon extract and many other essences and flavouring fluids.

3. Methyl alcohol is largely used in the preparation of many proprietary and patent medicines, witch hazel, domestic liniments, as well as hay rum, Cologne water, Florida water and other perfumes.

4. The injury to the eyesight consists chiefly of a destructive inflammation of the optic nerve or of the retina (or both) followed by their atrophy.

5. The symptoms of acute poisoning are disturbances of the stomach more or less severe, accompanied by abdominal pain, general weakness, nausea, vomiting, dizziness, headache, dilated pupils and blindness. If recovery does not occur, there is marked depression of the heart's action, sighing respiration, cold sweats, delirium, unconsciousness, coma and death.

6. The blindness affects both eyes and may set in a few hours after the contact with the poison, or it may be delayed for several days. It is generally complete, with a subsequent improvement and, finally, a relapse into permanent blindness.

7. The diagnosis can hardly be mistaken. Methyl alcohol poisoning presents a picture unlike that of any other intoxication. Acute abdominal distress, followed by blindness, should always awake suspicion of methyl alcohol poisoning.

8. The prevention of poisoning by this insidious drug can only be brought about by prohibiting (or rendering unprofitable) the sale of "deodorized" wood alcohol in all its forms. The number of deaths may, meantime, be limited by putting all preparations containing wood alcohol on the list of poisons and prosecuting all persons adulterating foods and drinks with it. Labelling it with the notice, "This fluid taken internally is likely to produce blindness," will certainly have a deterrent effect.

9. Wood alcohol intoxication is an example of idiosyncrasy. As in the case of several other poisons, some persons are largely immune so far as permanent damage to the body is concerned. If ten persons drink, say 4 ounces of Columbian spirits within three hours, all will have marked abdominal distress and probably four will die, two of them becoming blind before death. Six will eventually recover, of whom two will be permanently blind. With still larger doses, the proportion of death and blindness will be greater.

Commenting on the death of four men and the blindness of one man in Whitestown, Indiana, about August 16th, 1911, Dr. P. B. Little of that town writes me:—

"It seems that these men purchased and made a mixture of one gallon of wood alcohol and 3 gallons of grain alcohol and all drank freely of it. The symptoms that followed soon after were chiefly headache, nausea, vomiting, extreme weakness, clammy sweats, weak pulse, blindness, dilated pupils, cyanosis, sighing, respiration, convulsions and death. The blindness came on six to eight hours before death. The survivor of this debauch was the first to fall sick and the first to become blind."

References.—Journal of the American Medical Association, December 7th, 1912, page 2075; May 10th, 1913, page 1479; March 18th, 1916, page 913.

We may revert now to my claim earlier in this paper that methyl alcohol is highly toxic and for that reason the Revenue Authorities should have no fear that it can be consumed as "potable spirit." Then why tax it as "plain spirits"? Why penalise British chemical industry by taxation of a "key" chemical? One may suppose that if methyl alcohol had been called by some other less alcoholic name it would never have been classified as "spirits" at all.

During the inquiry of the Departmental Committee on Industrial Alcohol (1905) the question of the toxicity of methyl alcohol never seems to have been raised. There is, moreover, a curious omission in the Report of the Sub-Committee that visited Germany. They make no comment on their own statement that methyl alcohol in Germany is free from all Revenue control.

Yet to the British Revenue Authorities methyl alcohol is "spirit." Why could Germany afford to ignore methyl alcohol as being "potential whisky"? This same Sub-Committee enthused over the "pre-eminence long enjoyed by Germany in the manufacture of pharmaceutical products—fine chemicals."

Does the Sub-Committee enlighten us on the use the German fine chemical manufacturer made of the "spirit" which was for him really duty-free? Did they ask if the German-made alkaloids were crystallised from pure methyl alcohol over which there was no Revenue control or from ethyl alcohol over which the supervision was strict and costly? If they did the reply is not printed.

I suggest that henceforward pure methyl alcohol should be known by its scientific name of "Methanol" and that it be labelled "Poison."

As a further safeguard let the Customs Board be authorised to sanction its use under the same conditions that apply to-day to the use of industrial alcohol and free from all further taxation and Revenue control.

With these recommendations and the following references to the literature on the toxicity of methyl alcohol I close my case.

ABSTRACTS OF LITERATURE REFERENCES.

POINCARÉ. (Compt. rend., **87**, 682.) *Danger of employing methyl alcohol in certain industries.* Some animals which had remained from 8 to 16 months in an atmosphere continually renewed, but charged with a certain quantity of methyl alcohol vapour, were afflicted with great increase in size of the abdomen, together with other serious symptoms. On examination after death, there was found to be considerable hypertrophy of the liver, which filled the greater part of the abdominal cavity; a fatty degeneration of this organ to an extent that could be scarcely exaggerated: an alteration of the constitution of the muscular fibres of the heart, of the epithelial cells, of the uriniferous tubes, and of a large number of the cells of the lungs.

POHL. (Chem. Centr., 1893, ii., 380—381; from Arch. Expt. Path. Pharm., **31**, 281—302.) *Oxidation of methyl and ethyl alcohols in the organism.* Methyl alcohol administered to a dog produced protracted sleep, and when this passes off, the dog awakes in a normal condition. Methyl alcohol, on the other hand, produces restlessness, giddiness, and then broken sleep; and the effects of a dose last for three or four days. A dog may be dosed without harm for a year with ethyl, isobutyl, or amyl alcohol; but with methyl alcohol death ensues in a few weeks. In the case of poisoning by methyl alcohol, formic acid appears in the urine, and reaches a maximum on the third or fourth day.

BOKORNY. (Pflüger's Archiv, 1897, **65**, 114—144.) *Carbon compounds as food material for bacteria.* Methyl alcohol appears to be a fairly good source from which bacteria can obtain their carbon: ethyl and amyl alcohols can also be used.

MULLER. (Z. angew. Chem., **23**, 351—5.) *Methyl alcohol poisoning.* A lecture delivered before chemists.

LEWIN. (Chem. Zentr., 1911, i., 672; from Apoth. Zeit., 1911, **26**, 54—5.) *The toxic action of methyl alcohol.* The author gives many instances of the extraordinary toxicity of methyl alcohol which follows both inhalation and ingestion through the stomach. Of sixty-three hens' eggs, after injection of ethyl alcohol, nine did not develop at all; twenty-two developed monstrosities; after injection of methyl alcohol, nine did not develop, whereas forty-one gave rise to monstrosities.

FORSTER. (Bied. Zentr., 1911, **40**, 431; from Z. Spiritusind., 1910, **33**, 2.) *Action of methyl alcohol in the organism.* The stronger physiological action of methyl alcohol as compared with ethyl alcohol is perhaps due to impurities hitherto not detected.

SABBATANI. (Pharm. Inst. Parma. Arch. fisiol. (Fano's Festschrift), **7**, 49—80; through Zentr. Biochem. Biophys., **10**, 621—2.) *In what manner do ethyl and methyl alcohol influence the molecular concentration of the blood and the organs?* The value of the ratio of the change in Δ of the blood after the intravenous injection of EtOH, MeOH and NaCl to the minimal dose was found to be 6.4, 6.2 and 7.3 respectively. The cryoscopic value varies from normal in the organs, being very evident in the brain, evident in the kidney, and less pronounced in the heart. The muscles gave only a very slightly higher value, while that of the liver was lowered.

The electrical conductivity was lowered by alcoholic injections and increased by NaCl. A physico-chemical discussion of the results is given.

AXON. (Pharm. Zentralhalle, **52**, 335—6.) *Toxicity of methyl alcohol.* In view of the fact that 8 grms. of MeOH was found to affect the eyesight seriously and 15—30 times as much in one dose would kill, the introduction of MeOH into foods should be carefully guarded against.

HORBAEWAERD. (Oesterr. Chem. Ztg., **14**, 139—11; through J. Soc. Chem. Ind., 1911, 826.) *Injurious effect of alcohol denatured with wood spirit on workers' health.* The use of wood spirit should no longer be permitted for denaturing ETOH because the health of those working with such denatured ETOH is liable to be seriously affected by the impurities contained in the wood spirit together with the greater toxicity of the MeOH itself in comparison with ETOH. The use of shellac is advocated as a denaturing agent for alcohol for polishing and lacquering industries.

CORNALBA. (Boll. Chim. farm., **51**, 37—38.) *The toxicity of methyl alcohol.* Warning is issued against possible use of CH_3OH in pharmaceutical products. Cornalba notes authorities who claim that CH_3OH is not toxic, but himself leans to those who assert its poisonous properties. Method of detection of CH_3OH in $\text{C}_2\text{H}_5\text{OH}$ is given according to Riche and Bardy, modified by Jorissen and Torickanoff, as follows: After formation of methyl-aniline iodide, the excess of aniline is eliminated by shaking with ether. Fractional distillation is then employed, the first fractions are collected and dehydrated with dry K_2CO_3 and the boiling point detd. CH_3OH boils 13° below the b.pt. of $\text{C}_2\text{H}_5\text{OH}$.

FRANCESCHI. (Giorn. farm. chim., **61**, 145—52.) *A supposed poisoning by methyl alcohol and its chemical and toxicological research.* Résumé of poisonings by alcohol—Methyl, butyl, amyl—is given, as well as opinions of various authorities as to relative toxicity. Special notice is given to large numbers of deaths of inmates of a Berlin municipal lodging-house, due to drinking spirits made with wood alcohol. Details of technic are given, together with an outline of work planned to show relative toxicity of ETOH and MeOH on animals. Other chemicals, such as methylene compounds, formic ether, etc., will be tried and reported on later.

SCHMIDEBERG. (Therap. Monatsh., **26**, 329—31.) *Methyl alcohol poisoning.* THOMAS TYLER AND F. G. GOSLING. (Yr.-bk. of Pharm., 1912, 434.) *Notes on commercial formates and other compounds. Methyl alcohol.* The toxicity of this alcohol is now placed beyond doubt. Attempts to ascribe the toxic quality to other constituents of commercial methyl alcohol and wood naphtha have failed. Undoubtedly methyl alcohol is itself toxic, as well as some other constituents of the commercial methyl alcohol.

HARNACK. (Deut. med. Wochschr., **38**, 358—61.) *The poisonous properties of methyl alcohol.* MeOH, compared with other alcohols, acts less strongly. Its danger lies in the slow oxidation to HCOOH which occurs in the nervous tissues having a specific affinity for the alcohol.

MENDEL. (Berl. oph. Ges., Jan. 25th, 1912; Zentr. Biochem. Biophys., **12**, 941.) *Blindness caused by methyl alcohol.* Various cases of blindness are recorded.

VOLTZ AND DIETRICH. (Biochem. Zeitsch., 1912, **40**, 15—28.) *The part played by methyl and ethyl alcohols in the general metabolism of the animal organism.* The amount of methyl alcohol excreted in the expired air and in the urine was estimated. It was found that after administration of 2 c.c. of methyl alcohol per kilo. of the body weight to a dog, 24.3% was excreted in forty-eight hours, of which 21.5% was in the expired air, and 2.8% in the urine. As 36.5% was found in the body, it follows that only 39% was oxidised in the body. If the caloric value of the methyl alcohol oxidised is calculated, it will be found that this represents only 3% of the total metabolism of the body. These results are in marked contrast to those obtained with ethyl alcohol under analogous conditions. In this case 2 to 4% of the quantity administered was found in the expired air and 0.4 to 3.8% in the urine within 10 to 15 hours. After 15 hours only 3 to 12% was found in the body. Of the food-stuffs degraded within 10 hours, the ethyl alcohol (calculated on the caloric values) formed 42% and in 15 hours, 35%.

JUCKENACK, PRAUSE, GRIEBEL, JACOBSEN AND GAZA. (Z. Nahr. Genussm., **24**, 7.) *The Berlin methyl alcohol poisoning.* 79 deaths and 95 cases of sickness in Berlin were shown to have been due to methyl alcohol contained in brandy in the relation of 80 methyl to 20 ethyl alcohol. In the qualitative test for methyl alcohol the method of Fendler and Mammich (Apoth. Ztg., **20**, 569) was used. For the quantitative determination resort was made to the determination of the carbon present, the difference between the carbon content of ethyl and methyl alcohols being 14.68%. The presence of methyl alcohol was also demonstrated in the dead body, and HCO_2H was likewise found.

NICLOUX. (Orig. Com. 8th Intern. Congr. Appl. Chem., **19**, 259—60.) *Determination of methyl alcohol in the blood and tissues.* Method based on oxidation with $\text{K}_2\text{Cr}_2\text{O}_7$ and determination of the resultant CO_2 . The ratio CO_2/O_2 is specific (0.915 part methyl alcohol). The figure obtained in the experiments coincided with this ratio.

WHITNEY. (Amer. J. Physiol., 1912, **30**, 463—465.) *The relative toxicity of methyl and ethyl alcohols as determined by the rate of reproduction in Hydratina senta.* Methyl alcohol is less toxic than ethyl alcohol, as determined by the rate of reproduction in the rotifer, *Hydratina senta*. Families subjected to 1% methyl alcohol during many (10 to 15) generations recover from its influence in the second generation after the alcohol is removed.

RÜBLE. (Münch. med. Wochschr., **59**, 964—7.) *Findings in the central nervous system of experimental animals after methyl alcohol poisoning.* Two dogs were killed acutely by C.P. methyl alcohol (one animal was given 450 c.c. in 4 hours and died in 38 hours; the second, 250 c.c. in 24 hours and died in 18 hours). All the preparations examined revealed scattered hemorrhages around blood vessels in the pons, the medulla oblongata and the

spinal cord, partly lodged between the medullated fibres and partly between the ganglion cell groups. Preceding these perivascular hemorrhages were seen leucocytic accumulations and loading of the vascular endothelium with lipoids.

TYSON. (Arch. Ophth., 1912; Zentr. Biochem. Biophys., **15**, 205.) *Amblyopia from inhalation of methyl alcohol.* Peculiar anomalies in the field of vision are described.

GRIGNOLO. (Klin. Monatsbl. Augenheilk., **51**, 157; Zentr. Biochem. Biophys., **14**, 889.) *Biochemical changes in the aqueous humor in acute methyl and toxipeptide poisonings.* Osmotic pressure in the aqueous humor increases after methyl alcohol poisoning, while H^+ remains unchanged and the H^+ concentration is only slightly modified. In peptone poisoning, osmotic pressure, H^+ and H^+ concentration experience no change.

KASASS. (Inaug. Diss., St. Petersburg, 1912; Zentr. Biochem. Biophys., **15**, 205.) *Pathology of methyl alcohol amaurosis.* Methyl alcohol causes blood extravasation in the sheaths of the optic nerve and choroid, thus producing circulatory disturbances; through incomplete combustion of methyl alcohol formic acid collects in the vessels and causes fatty degeneration. These two factors, together with oedema, lead to degeneration of the retina and consequently to rapidly ensuing blindness. If the collateral circulation be restored, oedema disappears and visual power partially returns. Central scotoma depends on axial neuritis while diminution of the field of vision is due to affection of the peripheral end of the optic nerve.

SEGALE. (Accad. med. Genova (session Feb.), 1912; Zentr. Biochem. Biophys., **14**, 446.) *Acute experimental intoxication due to methyl alcohol and differential biochemical diagnosis of acute poisoning of the toxipeptide type.* The author reviews his previous investigations of poisoning by toxipeptides. It is possible from the refractometric data and by means of the determination of the H^+ ion concentration of serum to differentiate toxic diseases from methyl alcohol poisoning, which has practically the same symptomatology.

NICLOUX AND PLACET. (J. physiol. path. gen., **14**, 916.) *Toxicity of methyl and ethyl alcohols.* Large intravenous doses of methyl alcohol are relatively less toxic than ethyl alcohol. The greatest alcohol retention is found in brain tissue. In repeated small doses every 24 hours, methyl alcohol is more toxic than ethyl alcohol. This appears to be due to the cumulative effect obtained since methyl alcohol is eliminated more slowly and is less readily destroyed in the tissues than ethyl alcohol.

BERGER. (Chem. Ztg., **36**, 524—5.) *Methyl alcohol poisoning.* A review of the history, chemistry, pharmacology, and toxicology of MeOH, and a discussion of laws relating to its manufacture and sale.

LANGGAARD. (Chem. Zentr., 1912, ii., 1382—3; from Berl. klin. Woch., 1912, **49**, 1704.) *The poisonous nature of ethyl and methyl alcohols.* Methyl alcohol is more poisonous than ethyl alcohol when taken in repeated small quantities, but ethyl alcohol is much more dangerous when taken in a single large dose.

MURA. (Biochem. Zeits., 1913, **49**, 144—151.) *The action of methyl alcohol on the circulating blood.* In 2 out of 5 experiments (on 4 rabbits and 1 dog) injection of methyl alcohol produced anaemia. There was observed a diminution of lymphocytes and an increase in the number of pseudoeosinophile or neutrophile corpuscles and also haemoglobinuria. The methyl alcohol appears to act toxically on the blood-forming apparatus.

FRANCESCHI. (Boll. chim. farm., **51**, 325—9.) *A suspected poisoning by methyl alcohol and the chemical-toxicological investigation of the same.* A detailed discussion of the chemical-toxicological examination made on the body of C. Franchini, a victim of wood alcohol poisoning.

BOESEKEN AND WATERMAN. (Chem. Weekblad., **9**, 694—6.) *Remarks concerning the poisonous properties of methyl alcohol.* Experiments with several varieties of moulds showed that MeOH as a source of carbon is less suitable as a food for the moulds than the corresponding ethyl alcohol derivative. This is not due to physical properties like solubility, but to chemical properties, possibly to the conversion of the methyl alcohol derivative to formaldehyde which is a poison, while the ethyl alcohol may yield only the relatively harmless, easily polymerising acetaldehyde.

HIRSCHBERG. (Berl. klin. Woch., **49**, 245—51.) *Methyl alcohol whisky poisoning.* The author discusses the clinical progress of methyl alcohol poisoning, citing an extensive number of cases, and urges in conclusion, a more careful supervision of methyl alcohol whisky dispensation.

SEGALE. (Berl. klin. Wochschr., **50**, 255—6.) *The biochemical differential diagnosis between toxipeptide and methyl alcohol poisoning.* In acute poisoning with toxipeptides the osmotic pressure, the ionic concentration and the refractive index are increased, the electrical conductivity is little changed, and in acute poisoning with methyl alcohol the osmotic pressure becomes high, the concentration of the ions is unchanged, H^+ is reduced, and the electrical conductivity is little affected.

OLIVARI. (Chem. Zentr., 1913, i., 1780; from Arch. Farmacol. sperim., 1913, **15**, 83—96.) *Poisoning by methyl alcohol.* The toxicity of crude and pure methyl alcohol for frogs, mice, and guinea-pigs was investigated. In the case of the pure product, the minimal lethal doses were: for frogs, 10.2%; for mice, 11.5%; and for guinea-pigs, 9.5% of the body weight; the corresponding numbers for the crude acid product were 10.0, 7.5, and 6%; and for the crude base product, 8.6, 6.8, and 5.5%. A scheme is given for the forensic examination of drinks and animal organs in which wood-spirit is suspected. The liquid is acidified with phosphoric acid, and the volatile acids, etc., are distilled off, whilst the bases (pyridines, amines, etc.) remain in the residue. The distillate containing the acids is neutralised, and again distilled, the salts of the acids remaining behind, the aldehydes, etc., distilling over. These are fixed by *m*-phenylenediamine hydrochloride and the mixture is distilled, when acetone and methyl alcohol distil over, and are estimated in the distillate. If the

mixture is saponified before these treatments, a conception can be formed as to the quantity of esters present from the amount of alcohol in this distillate. Finally, ethereal oils can be extracted by mineral oils (b. pt. 140° – 230°), and separated from the higher alcohols by fractional distillation.

NICLOUX AND PLACKET. (Compt. rend. soc. biol., 73, 63–6.) *Comparative toxicity and elimination of methyl alcohol and ethyl alcohol.*

LOWRY AND VON DER HEIDE. (Biochem. Zeitsch., 1914, 65, 230–252.) *The intake of methyl alcohol in inspiration.* Rabbits and dogs were exposed in a respiration chamber to air containing various quantities of methyl alcohol vapours. These amounts could be regulated by passing air through methyl alcohol in various dilutions in water. The air was measured by a meter, and the amount of alcohol was estimated at the beginning and end of the experiment. The toxic effects were noticed, and the alcohol in the animal bodies was estimated at the end of the experiment. In presence of only 0.2% of alcohol in the air, quite appreciable quantities were taken up by the organism. With alcohol of this tension, and up to 0.5%, the saturation of the animal body is reached in 2 hours. With higher concentrations, the times required for saturation are markedly longer, and when the tension reached 2%, the maximal amount is not taken up even after 8 hours. Fat animals under similar conditions take up less alcohol than lean ones. This is due to the small solubility of lipids in methyl alcohol; the coefficient of distribution between oil and water is about 2:100.

ASOX. (Pharm. Notisbl., 1914, 23; Apoth. Ztg., 1914, 639; Pharm. J., 93, 349.) *Determination of methyl alcohol and formaldehyde in urine.* To 10 g. urine add 2 g. pure H_2SO_4 , cool, add about 0.7 g. $KMnO_4$, enough to leave a slight rose tint after filtering. To 1 g. of filtrate add 4 g. pure H_2SO_4 , cool, then pour on it a solution of 0.05 g. morphine hydrochloride in 3 g. H_2SO_4 . A violet-coloured zone will indicate $MeOH$ or $HCHO$, up to a dilution of 1:5000 H_2O .

IGERSHEIMER AND VERZAR. (Arch. Augenheilk., 75, 27; Zentr. Biochem. Biophys., 15, 942.) *Pathogenesis of methyl alcohol and atoxyl amblyopia; experiments on the pathology of the perception of light.* Hens tolerated large amounts of 20–25% methyl alcohol; general symptoms of poisoning with the appearance of inebriation were observed. The retina showed no noteworthy alterations; severe lesions were produced by higher concentrations of methyl alcohol. Either a transitory or a gradually increasing diminution in the sense of light was observed; it was not ascertained whether such modification was due to changes in the retina or to cerebral fatigue. Atoxyl (5%) produced symptoms of poisoning of the central nervous system in hens. The structure of the cells of the inner retinal layers was altered; the sense of light was not affected.

NICLOUX. (Compt. rend. soc. biol., 73, 59–62.) *Determination of small amounts of methyl alcohol in the blood and tissues. Determination of its vapour in the air and means of characterising it.* Methyl alcohol may be determined in blood by adding 6–7 times the vol. of a saturated picric acid solution and distilling in a Schloesing-Aubin apparatus; all the methyl alcohol is found in a vol. of distillate equal to $1/15$ th the original vol. and may be determined therein by means of the $K_2Cr_2O_7$ method previously described by the author. In the case of urine or any other liquid of the organism an equal vol. of picric acid solution is taken; in the case of tissues, 10–20 grms. of the latter is added to approximately 40 c.c. of the picric acid solution, and cut into small bits while immersed therein, the distillation and determination being then carried out as above. Methyl alcohol may be determined in air by passing the latter through a series of 6–7 wash bottles containing water at ordinary temperature and then following the procedure described above. In order to differentiate between methyl alcohol and other substances oxidisable by chromic acid—the ratio of CO_2 produced to O consumed in the reaction is determined; the latter is calculated from the number of c.c. of $K_2Cr_2O_7$ solution employed, while the amount of CO_2 produced is ascertained by absorption in KOH (the reaction is allowed to take place in a specially designed, hermetically sealed tube and the CO_2 is then withdrawn by means of a mercury pump).

KROEGER. (Internat. Pharm. Cong., J. Pharm. Chim., 1913, 8, 371.) *Toxicity of methyl alcohol.* Pure methyl alcohol is not so toxic as is generally represented. Probably the poisonous effects attributed to the alcohol are due to traces of dimethyl sulphate present in it.

KROL. (Arch. exp. Path. Pharm., 72, 144–56.) *Methyl alcohol poisoning.* Ammonia determinations carried out on a dog with const. diet gave a considerable increase after addition of methyl alcohol. Only a small part of the ammonia was neutralised by formic acid; the principal amount was bound to an acid not yet investigated. Animals given 45, 55, and 60 grms. methyl alcohol showed an incomplete narcosis, rapidly disappearing. Blindness was not observed.

FELLENBERG. (Mitt. Lebensm. Hyg., 1915, 6, 24–37.) *The occurrence of methyl alcohol in urine in different kinds of nutrition.* Methyl alcohol in urine was determined by the author's modification of the Denisz method. On a pectin-free diet very small amounts of methyl alcohol occur in the urine (about 0.4–1.0 mg. per 750 gr.), and on a fast it is reduced one-half. On a diet rich in pectin the amount increased to 0.8–2.5 mg. The condition of the pectin, whether raw, containing pectase, or cooked and pectase-free, makes little difference in the methyl alcohol secretion. The use of ethyl alcohol in a pectin-free diet raises the methyl alcohol content slightly; with pectin there is a large increase. Cheap wines containing both methyl alcohol and ethyl alcohol cause a maximum rise. The author discusses briefly the pathological effects of methyl alcohol on the system.

TYSON AND SCHOENBERG. (Sect. Ophth. Am. Med. Assoc., June, 1914; Klin. Monatsbl. Augenheilk., 53, 252 (1914); Zentr. Biochem. Biophys., 17, 663 (1915).) *Poisoning by inhalation of methyl alcohol.* Pronounced manifestations of poisoning were observed in dogs, rabbits, guinea-pigs and monkeys which were

placed in a space in which methyl alcohol was vaporised. The effect on the eyes consisted of irritation of the conjunctiva and cornea, hyperemia and oedema of the papillae with dilatation of the blood vessels. Coma, with moderate myosis and fixed gaze, and pronounced hypotony in severe cases, was observed. The aqueous humor acquired an acid reaction. Blindness ensued in some instances. Degeneration of the retinal ganglionic cell layer occurred.

CHABANIER AND IBARRA-LORING. (Compt. rend. soc. biol., 1916, 79, 8–9.) *Erection of ethyl and methyl alcohol by the kidneys.* The concentration of methyl alcohol and ethyl alcohol (determined by the Nicloux method) was practically identical in the blood and urine of subjects who had ingested these compounds. Ethyl alcohol and methyl alcohol were, therefore, simply diffused and not concentrated by the kidneys. Substances excreted by the kidneys may be classified in two groups: (1) those such as urea, glucose, iodides, etc., which have been concentrated by that organ, and (2) those such as methyl alcohol and ethyl alcohol, which are eliminated in the urine in practically the same concentration as they occur in the blood.

RUGGERI. (Ligaria med., 7, 187; Zentr. Biochem. Biophys., 18, 361–2.) *Changes in lipid content in acute poisoning by methyl alcohol.* Both methyl and ethyl alcohols modify the lipid content of organs; for equal high concentrations methyl alcohol has the greater effect, while the changes produced at low concentration are practically the same for both alcohols. A considerable increase in the fatty acid and cholesterol content of the blood serum results from acute experimental poisoning with methyl alcohol. The complement action of the serum was diminished somewhat in acute experimental poisoning by ethyl alcohol, but this diminution was not as great as in methyl alcohol poisoning, probably due to greater effect on the lipoids and liver.

I am gratefully indebted to Dr. C. S. Roy and Miss C. Kern for assistance in preparing these references and abstracts.

TONICOLOGY OF METHYL ALCOHOL.

Extract from E. Merck's Annual Report, 1912, Vol. 26, p. 86.

In the past year a large number of observers have studied the question of poisoning by methyl alcohol, its various symptoms, its cause, its transient and permanent injuriousness, its fatal termination, and the dangers of methyl alcohol in general. These include, among others: Lewin, Rost, Levy, Strassmann, Foerster, Schenk, Ohlemann, Mendel, Hirschberg, Harnack, Grunow, Voltz, Keferstein, Kuhn, Burger, Pick, Schmiedeberg, Buchka, Ruhle, Kroeber, Schlichting, Langgaard, Lennhoff, Stadelmann. For all details, reference should be made to the original communications of these authors, as they cannot be considered here. It may, however, be noted that they show that methyl alcohol itself, when habitually used, or when taken in a single large dose, may act as a poison, so that the toxicity is not due to the presence of impurities in the preparation. The fact that some persons are able to take comparatively large doses of methyl alcohol without apparent harm does not militate against the toxicity of methyl alcohol. It is impossible to say beforehand how large a dose will display an injurious action. According to Ruhle the lethal dose varied between 50 and 100 grammes, but the toxic dose is much less, and blindness may ensue after doses of only 7 to 8 grammes.

I have to acknowledge with thanks the assistance of Mr. P. Alderton for these references.

DISCUSSION.

Mr. A. E. BERRY said that the supply of methyl alcohol at the present time was greatly in excess of the demand. He had been closely in touch with the authorities on this question and their view was that there was no duty on crude methyl

alcohol such as was turned out in the Government factories. It was only in the purified form that it came into the same category as ethyl alcohol. He wished to correct one mistake on the part of the author when he said that *pure* methyl alcohol was not produced in this country to any extent. That might have been true a few months ago, but he could assure him that it was being produced now and could be produced in considerable quantities. His own interest in it related to the manufacture of formaldehyde, for which pure methyl alcohol was necessary. For many years formaldehyde had been imported here free of duty, yet the British manufacturer had been handicapped because he could not have sufficiently pure methyl alcohol free of duty, and he was glad attention had been drawn to the matter. He had been working hard at the question for three years, but had not made very much progress with the Customs Authorities. Mr. Morson had said it required an Act of Parliament to change the prevailing condition of affairs, and he (the speaker) suggested that the Society should present a petition to Parliament, pointing out the industrial applications of methyl alcohol and presenting all the evidence as to toxicity in order to get them to free the hands of the Customs Authorities, who, he was sure, would be glad to be relieved of the incubus that was associated with the name "methyl alcohol."

Dr. R. LESSING said that it was not only the duty that was irksome, because in most cases it could be arranged that this should not be paid or it could be refunded. That, however, involved a restriction of the methods of distillation and placed a great handicap upon the chemical engineer, because it was necessary to arrange the plant for the convenience of the Excise officer rather than with a view to the best efficiency of the plant. There were no restrictions as long as the alcohol contained sufficient impurities, for instance, 2% of acetone, but as soon as this figure of purity was reached the authorities stepped in and assumed control of the process from that point. It was then a question of having that portion of the plant under lock and key, which did not permit of that elasticity of working conducive to obtaining the best results.

Mr. W. J. A. BUTTERFIELD referred to Dr. J. Ramboisek's book on "Industrial Poisoning," in the translation of which by Dr. T. M. Legge, the Chief Medical Inspector of Factories, published in 1913, the following passage relating to the toxicity of methyl alcohol occurred:—

"Methyl alcohol plays relatively the greatest part among alcohols as an industrial poison, because it is employed as a means of denaturing spirit. Its poisonous nature is relatively great, being very persistent. Industrial poisoning by methyl alcohol is due to inhalation of the vapour and is rarely of a severe nature. The fumes have a strongly irritant effect upon the mucous membrane, giving rise to throat irritation, cough, hoarseness, and, in severe cases, bronchitis and inflammation of the conjuncture of the eye. In addition, inhalation of methyl alcohol vapour causes headache, giddiness, nausea (inclination to vomit), and occasionally also twitchings and tremor."

Mr. PROCTOR did not think the evidence as to toxicity of methyl alcohol was more than could be obtained with regard to the toxicity of ethyl alcohol, but if the case was proved against methyl alcohol it was probable that the Customs restrictions would be replaced by the more irksome poisons regulations. The question was not a simple one, there being a great many side issues which made the position of the Excise authorities very difficult. Mr. Morson had said that if he could get methyl alcohol duty free as readily as ethyl alcohol, it would meet his case. He (the speaker) did not

think there was any difficulty in this respect. If manufacturers generally made themselves acquainted with the regulations under which both methyl alcohol and ethyl alcohol could be obtained duty free, they would not find the difficulties so great as they imagined. In both cases denaturants were required, but many different denaturants could be used and manufacturers could generally suggest something used in their process which the Excise authorities would be quite ready to accept.

The CHAIRMAN asked whether the author had any evidence of the course of oxidation which methyl alcohol undergoes in the body, as this was a fundamental point in connection with its toxicity. It was known that alcohols acted upon the nervous system as narcotics, but methyl alcohol seemed to be exceptional in its physiological as in its chemical reactions, and it might be that this was due to a partial initial oxidation to formaldehyde or to formic acid. It was to be borne in mind that the term "toxicity" was a total effect and gave little indication of the action of a poison without some knowledge of the metabolic changes involved.

Mr. MORSON, in reply, said he was not able to answer the Chairman's question. The evidence from the literature was certainly in one case that the effect was due to oxidation to formaldehyde, which exercised a powerful chemical influence. In the other case it was due to slow oxidation to formic acid, but beyond that he was equally in the dark as to why it was so toxic. There was, however, the whole mass of evidence from physiologists and American medical men as to the intensely toxic effects, and if Mr. Proctor would look into that evidence carefully he would come to the conclusion that it was strong, especially when he saw the American pamphlets. The Americans had done an enormous amount of work, whereas we had not begun, and he claimed there was overwhelming evidence that methyl alcohol is highly toxic. Mr. Proctor had not answered the question as to why it should be taxed. It could not be used as a substitute for whisky or as a potable spirit at all without fatal results, and in that respect it certainly differed from ethyl alcohol. As to Mr. Berry's remarks, methyl alcohol became dutiable if it contained under 2% of acetone. He was glad to hear from Mr. Berry that there was going to be plenty of methyl alcohol; the statement in the paper on the point was not his but came from a firm of wood distillers. The question of the petition to Parliament need not be taken up yet, because he hoped the action of the manufacturers would go further.

November 28th, 1917.*

DR. R. M. CAVEN IN THE CHAIR.

POISONS AND DRUGS OF ANIMAL ORIGIN.

BY GEORGE BARGER.

The protective poisons which occur in many groups of animals have mostly not been isolated in a state of chemical purity. Generally, however,

we have at least some conception of their chemical nature. Thus cobra-venom contains a nerve-poison, which paralyses the respiratory centre, and also a hamolytic principle. The former, ophiotoxin, has, according to Faust,¹ a composition corresponding approximately to the formula $C_{15}H_{25}O_{10}$ and resembles the saponins in physical properties; anyhow it seems to be nitrogen-free. The hamolytic substance is, according to Manwaring³, a lecithinase, an enzyme which splits off one of the fatty acid groups of the lecithin contained in the victim's blood, and this partially hydrolysed lecithin is known to be hamolytic. Previously Kyes³ had imagined that when snake-venom is shaken with a lecithin solution, a compound soluble in chloroform is formed, in which one of the fatty acid groups of lecithin is replaced by an active constituent of snake-venom, to form a so-called lecithide.

The active principle of a toad has, on the other hand, been obtained crystalline and quite pure. A few years ago Abel and Macht⁴ isolated from the so-called parotid skin gland of the large central American toad, *Bufo aqua*, a substance which undoubtedly has the composition $C_{15}H_{24}O_4$; it has a very powerful digitalis-like action on the heart and is also a diuretic. These authors have thus found a scientific basis for the former great reputation of powdered toad skins as a cure for dropsy. Their use for this purpose now only survives in China under the name of "senso," a drug which Shimizu⁵ has lately shown also to contain bufagin. The parotid secretion of *Bufo aqua* is further remarkable in containing over 5% of epinephrine (adrenaline) identical in every respect with that obtained from the suprarenal gland of the higher animals.

Whilst bufagin of the toad and apparently also ophiotoxin of the cobra are neutral non-nitrogenous substances, the skin of the newt, *Salamandra maculosa*, contains two alkaloids, which Faust⁶ has isolated as crystalline sulphates. They are samandarine, $C_{26}H_{40}ON_2$, and samandaridine, $C_{22}H_{31}ON$; both are powerful nerve poisons. From the latter base Faust claims to have obtained isoquinoline by distillation with zinc dust.

The difficulty of obtaining enough material is often a great hindrance in chemical work on animal poisons and is illustrated by Langer's⁷ investigation of the poison of bees. This author collected 25,000 bee stings; but since the drop of poison ejected from a sting weighs only 0.2–0.3 mgrm. and consists mostly of water, only a few grams of the crude poison was obtained. The active principle in this case gives strong precipitates with alkaloidal reagents, but does not appear to be a protein.

More important than the protective poisons of the lower animals, of which a few examples have been given above, are the products of the so-called ductless or endocrine glands. These internal secretions, called by Starling hormones ("chemical messengers"), have been studied, especially in the larger mammals, including man, and some of them have of late years come into prominence as very potent and specific drugs. The remedial administration of the whole gland or of an extract has given rise to the name organotherapy. So far the preparation of the pure active principle on an industrial scale has only been accomplished in the case of the suprarenal gland. Two years after the isolation of adrenaline by Takamine⁸ in 1901, its synthesis was patented by Meister, Lucius, and Brünig (Ger. Pats. 152,814 and 157,300). Chlor-aceto-catechol is combined with methylamine and the ketone is then reduced to the secondary alcohol. Since, owing to the slight physiological activity of *d*-adrenaline, the synthetic racemic substance was found to have not much more than half the activity of the natural *l*-variety, the Höchst firm had the enterprise to effect a resolution on the industrial scale by means of the bitartrates

(Ger. Pat. 222,451). The dextro-enantiomorph is not allowed to become a waste product, but is again racemised by heating with dilute acids (Ger. Pat. 220,355). Several other syntheses have been patented, chiefly by the same firm, but they do not appear to be of practical value (Ger. Pats. 155,632, 185,598, 189,483, 193,634, 195,811, 209,609, 209,610, 209,962, 212,206, and 216,640), nor have the closely related substances arterenol, homorenol, and epinine found a wide application as substitutes for adrenaline, although their physiological activity is in most respects qualitatively similar. The synthesis, involving a stereo-chemical resolution, may appear complicated, but it should be remembered that a pair of bullock's suprarenals together contain only 30–40 mgrms. of adrenaline, or about 0.2% (in marked contrast to the 5–6% contained in the parotid secretion of *Bufo aqua*, referred to above). On the other hand the drug is extremely active and it is said that by some physiological reactions as little as 0.000002 mgrm. may be detected.

A second important ductless gland is the thyroid. Its oral administration, introduced in 1891 by Murray, appears to be a complete remedy in those diseases where the natural secretion is defective (myxoedema, cretinism) and constitutes the greatest triumph of organotherapy. The chemical constitution of the active principle has not been established until quite recently. Baumann⁹, who more than 20 years ago discovered the iodine content of the thyroid, obtained from it by boiling with dilute sulphuric acid an amorphous impure substance iodothyron, with 9–10% of iodine. The statements as to the physiological activity of this substance are conflicting. The same may be said of a protein, thyroglobulin, obtained by Oswald.¹⁰ Recently Kendall¹¹ has employed alkaline hydrolysis, with greater success, and a paper has been announced entitled, "The isolation and identification of the iodine-containing compound which occurs in the thyroid" (J. Ind. Eng. Chem., Oct., 1917, p. 985). Previous papers by the same author¹¹ have indicated that the free base contains 65% of iodine, its sulphate 60%. The molecular weight of the base is about 586. A photomicrograph of the crystals has also been published. The base is active in cretinism in very small amounts and the limit of tolerance is 2 mgrms. daily. The substance seems to be an indole or tryptophane derivative, and this would explain previous statements in the literature that iodized blood proteins have a physiological action like that of the thyroid gland.

If the constitution of the thyroid active principle has been definitely established, its industrial syntheses will be an important problem. By the use of a synthetic preparation the difficulties of dosage might be overcome, which at present result from the variability of the gland in animals. The standardisation of thyroid preparations has so far only been carried out by physiological means; their iodine content does not afford a sufficient indication of activity.

Reid Hunt¹² has devised a peculiar and very sensitive method for recognising the activity of thyroid preparations; he finds that very small quantities of the active gland increase the resistance of mice to the toxic effects of acetonitrile; as little as 0.1 mgrm. of the gland may double their resistance to this poison. By this means Hunt claims to have proved the presence of the thyroid secretion in the blood of sufferers from Graves' (Basedow's) disease, which is generally regarded as due to an excessive functioning of the gland. A more recent and probably simpler method of testing, which illustrates the effect of the active principle on metabolism, is due to Guder-natch¹³ and consists in feeding the thyroid preparation to tadpoles. The latter diminish in size, the tail becomes absorbed, and at the same time

development is accelerated, so that rudiments of the legs appear earlier than in the controls. This method has even been recommended for the standardisation of commercial preparations. (Photographs, illustrating it, will be found, for instance, in a paper by Rogoff and Marine, *J. Pharmac. exp. Therap.*, 1906, 9, 57). By means of the tadpole method Marine and Rogoff¹⁴ have shown that when potassium iodide is injected intravenously into an animal with a defective (iodine-free) thyroid, the iodine is fixed by the gland almost immediately, but it takes about 16 hours before this iodine is converted into the physiologically active substance.

On account of its wide-spread occurrence we may here briefly mention goitre ("Derbyshire neck"), the commonest disease of the thyroid, although it is not connected with a defective secretion of the active principle. The dispute as to the cause of this disease has lately been settled by McCarrison, who attributes it to an infection by an organism from the soil and from drinking water, thus explaining its endemic occurrence in many parts of the globe, while in other regions it is rare or absent. Closely associated with the thyroid gland and often embedded in it are the parathyroids, small organs, which seem to be even more important to life than the thyroid itself. Nothing is known about their active principle. After removal of the parathyroids the urine contains considerable quantities of methylguanidine (Koch¹⁵).

The pituitary (hypophysis cerebri) is another very important ductless gland. It consists of an anterior nervous, and a posterior infundibular portion. Its situation under the brain makes its experimental extirpation difficult, and attempts in this direction have not thrown much light on the functions of the parts. One of these functions is an influence on growth; the rare disease acromegaly, characterised by an enlargement of some bones (of the lower jaw, hands, feet, etc.), is associated with lesions of the pituitary. Brailsford Robertson¹⁶ has recently extracted a substance from the anterior lobe, for which he claims that it has a definite effect on the growth of mice, making them heavier and sturdier, although not larger, than the controls. This substance, tethelin, is a phosphatide with nitrogen and phosphorus in the ratio 4N : P, but probably not pure.

More than the anterior, the posterior portion of the pituitary has attracted the attention of physiologists. Its extracts have a pronounced action on the blood pressure, on the isolated uterus, on the kidney, on the mammary gland, etc. The pressor action of the pituitary was discovered by Oliver and Schäfer¹⁷ almost simultaneously with that of suprarenal extracts. The rise of blood-pressure is smaller, but more persistent than that due to adrenaline. Whether the diuretic action, discovered later, is due to the same or to a different hormone is not known, and the same may be said of the powerful action of infundibular extracts on the uterus, which was discovered by Dale¹⁸ and has of late been applied therapeutically with great success. Various indications, however, point to there being several active principles. Unfortunately no active substance has been isolated in a state of undoubted purity. Most is known about the properties of the pressor substance; it can be boiled in neutral or slightly acid solution without much loss of activity, but is rapidly destroyed by alkalis. It is also destroyed by trypsin, whence it would seem to be a peptide. It is insoluble in absolute alcohol and other organic solvents and is readily adsorbed by charcoal and by precipitates formed in its solutions and thus it is carried down by phosphotungstic acid. The action of pituitary extracts on the uterus, resembling that of the ergot sub-

stance β -iminazolyethylamine, and the fact that pituitary extracts, like this glyoxaline, give a diazo-reaction, has led to speculations concerning a similarity in the constitution of the two substances. Guggenheim¹⁹ condensed β -iminazolyethylamine with various amino-acids, forming dipeptide-like substances which, however, only had a slight activity. Some years ago Fühner²⁰ stated that Meister, Lucius, and Brüning had obtained by means of phosphotungstic acid four crystalline sulphates, all physiologically active (compare *Ger. Pat.* 268,841). Various others have claimed to have isolated an active principle, e.g., Baudouin²¹ and Bouin and Ancel²², but none of these claims seems to be well founded. It is possible that all the four Höchst bases were contaminated with a highly active substance; it is at least significant that these bases have not been characterised chemically. The isolation and the determination of the constitution of the pituitary active principle is evidently a matter of great difficulty, but would undoubtedly be of great value, particularly if it were followed by synthetical manufacture.

In reviewing drugs of animal origin we must finally draw attention to the immune sera, the production of which forms a peculiar and highly specialised branch of chemical industry. Of these anti-diphtheritic and anti-tetanic serum are by far the most important, the former in times of peace, the latter during the present war. They are obtained by injecting the filtrate from cultures of bacilli into horses. The soluble toxin renders the horses immune and their blood is subsequently found to contain so-called anti-toxin, sufficient to neutralise large quantities of the toxin. By periodic bleeding and separation of the serum, a highly specific and very valuable remedy is obtained. The anti-toxins, like the toxins, are unstable and very complex substances; their isolation seems to lie quite beyond the present bounds of chemical knowledge.

The high hopes raised at first by the success of diphtheria anti-toxin have not been wholly fulfilled, as regards the treatment of other bacterial diseases. In most cases the organism does not secrete a soluble poison into the culture medium, and hence weakened or killed cultures are injected. Then a so-called bacteriolytic serum may result, e.g., with cholera cultures a serum dissolving cholera vibrios. Among bactericidal sera, obtained in a similar way, we may mention those against streptococci, pneumococci, typhoid, and cholera, which are still more or less in an experimental stage; perhaps the anti-meningococcus serum is of most importance in this group. In a few cases immune sera have been employed successfully against non-bacterial toxins. The anti-venin of Calmette is an efficient protection against snake bite, but the difficulty here is that the immune serum against one species of snake does not protect against the bite of another species. A further interesting non-bacterial anti-serum is that from animals immunised against pollen grains; it is used to combat hay-fever.

PROF. J. W. COBB IN THE CHAIR.

APPROXIMATE ESTIMATION OF TAR FOG IN GAS.

BY ALFRED EDWARDS.

The estimation of tar fog in gas presents some difficulty. It is not easily and completely removed by filtration in a bulk sufficient to weigh; evaporation renders the true weight uncertain. Correct samples of the gas and tar fog are not withdrawn from the gas stream as readily as one might expect. A critical examination of the problem indicates that only under specified conditions can the sampling be correct, owing to the non-homogeneous character of the flow and the momentum imparted to the fluid particles by velocity. These conditions require the sampling orifice to face the current at a point of mean velocity, and the flow through the orifice to be the same in speed as that of the main flow.

When I was asked to determine the efficiency of a tar fog extractor, the conditions defined for accurate results seemed so impossible to reproduce that approximate methods were sought. A crude means of indicating the presence of tar fog is to allow the gas, issuing at high velocity, to impinge upon a white surface. Attempts have been made to render a visual comparison of the resulting stains a basis for a roughly quantitative comparison between two similar streams. Visual methods of this character are decidedly preferable in technical work if they can be made quantitative as well as comparative. The variation finally adopted was to draw the gas through ordinary filter paper of stout substance and measure the increased density to light produced by the stain.

If we then know the area of the stain on the filter paper (A), the density of the stain (D), the weight of tar to give unit density on unit area (T), and the volume of the gas (V_g), the quantity of tar fog present in the gas is $A \times D \times T \div V_g$ and may be expressed in grains per cubic foot or grams per cubic metre according to the particular units taken.

T is determined by suspending the tar, collected at the point considered, in solvent naphtha or similar colourless liquid and measuring the density in a glass cell with parallel sides.

If then W is the weight of tar taken, V the volume of solvent in which W is dispersed, V_c the volume of cell, A the area of side of cell, and D the density of tar and liquid in cell, the weight of tar to give unit density if spread over unit area is :—

$$W \div V_c \\ V \times A \times D = T.$$

The instrument by which the density to light is measured is one intended for the measurement of silver deposits in photographic negatives. Its use in addition to this specific purpose I have extended to the determination of various substances, where in fact the estimation can be reduced to one of density to light, with such good effect that I have no hesitation in recommending it as an essential part of the equipment of any laboratory. It is sold under the name of the "Density meter" by Sanger Shepherd and Co., and is a comparison photometer of very simple construction. Two apertures are viewed in such a way that they appear disposed side by side. A translucent object placed over one of the holes obstructs the light passing to one half of the field of view, and its intensity can be balanced by means of a neutral tinted pigment wedge deposited on glass placed over the other hole. The wedge is graduated in terms suggested and used by Hurter and Driffield in their classical photographic researches, density = log. opacity, opacity being the ratio the incident light bears to the transmitted light. The density of neutral tinted bodies can be balanced exactly by the instrument. When the body is coloured and transparent, the density to its complementary colour can be measured by viewing the aperture through a transparent screen of the correct colour. The coloured body is, in effect, converted into a neutral tint and can easily be balanced against the neutral wedge. Where an opaque body is present in a transparent coloured fluid, the aperture is viewed through a screen of the same colour as the fluid, and the opaque body balanced by the wedge. The instrument thus becomes a cheap, if crude, substitute for the spectro-photometer.

As an example of the determination of T (weight of tar per unit area to give unit density) the figures given in the following table were obtained. The density measurements were made in a glass cell of which the parallel sides were 10.2 mm. apart, the capacity 5.55 c.c. and the area of the side 5.441 sq. cm. 0.6674 grm. of tar was suspended in 50 c.c. of solvent naphtha and portions were diluted to 50 c.c. before measurement.

Density to light.

	2 c.c.	4 c.c.	6 c.c.	8 c.c.	10 c.c.
Red	0.37	0.77	1.13	1.51	1.87
Green	0.63	1.23	1.75	2.27	2.70
Blue	0.82	1.52	2.18	2.70	—

Density for 1 c.c. calculated from above.

Red	0.185	0.192	0.183	0.189	0.187
Green	0.315	0.307	0.291	0.284	0.270
Blue	0.410	0.389	0.363	0.337	—

It will be observed that the density to red light is in this case fairly even throughout the range; with green and blue light there is a gradual falling away.

Taking the average density for 1 c.c. to red light we have the following facts:— $W=0.01335$ gm., $V=50$ c.c., $V_c=5.55$ c.c., $a=5.441$ sq. cm., $D=0.188$.

$$T = \frac{0.01335 \times 5.55}{50 \times 5.441 \times 0.188} = 0.00145 \text{ gm. per sq. cm.}$$

The value of T varies for tars produced by carbonisation in various systems, and with the temperature of carbonisation in any one system. If the density does not increase in simple ratio with the weight, the points may be plotted and intermediate values read from the graph.

Sampling the gas.

The gas is filtered through a disc of filter paper cut by a cork borer or similar implement to a diameter of 1.8 cm. The disc is held between the ends of metal liners, 1.6 cm. diameter, sliding within a screwed metal nipple, thus exposing 2 sq. cm. of filtering area. A rubber washer is placed below the inner liner to secure tightness to gas as indicated in the figure. The nipple is screwed $\frac{3}{4}$ inch gas pipe, and enters a cock screwed hard up to the gas main. It is important that the connection should have a small volume, and that the filter paper should be as close to the gas stream as possible. A $\frac{3}{4}$ inch brass cock, full way, with male and female ends, screwed directly into the main, provides the shortest convenient connection. In order to ensure a fairly representative sample of the gas the sampling must be rapid to prevent the falling out of the larger tar particles. With

this object the difference of pressure between the two sides of the disc should be from 12 to 24 inches water column, depending upon the resistance of the paper disc. Speed is also necessary to complete the removal of the finer particles of fog by impingement within the pores of the filter paper. One disc only is necessary. A second one placed in series with the first and spaced by a metal liner is invariably unstained. The stain is always confined to the receiving surface of the first disc. Where the gas is under low pressure an aspirator is used to give the required pressure difference.

The volume of gas to be passed through the filter paper to give a stain within measurable limits, say 0.4 to 1.2, varies from 80 c.c. to 9000 c.c. depending upon the proportion of tar fog present. With the smaller volume the results become doubtful, since the volume of the voids in the connection and nipple bears an ever-increasing proportion to that of the gas sampled as the latter

becomes smaller. If the filter paper is of uniform texture and the connections short but of ample diameter, the stain obtained is evenly distributed. Very slight inequalities are averaged out by the density meter.

It is important that diffused light only should be used for measurement. Small pieces of ground glass covering the apertures and below which the filter paper or cell is placed secure this condition. Circles cut from the same sheet of paper have usually the same density and balance one another if placed over the two apertures. Of a set prepared for estimation, one disc is retained as a blank and divergent densities of others recorded and allowed for when the stain is measured, which should be with the blank in position over the wedge aperture. It is advisable to retain a second disc, which has been balanced against the blank, in order to check the setting of the density instrument.

It is not advisable greatly to exceed unit density of stain on the filter paper. Although the measurement in a glass cell to a density of about 1.5 usually increases evenly with the weight of tar present, the uniform conditions of dispersion under which the soluble and insoluble portions of the tar are viewed, cannot be obtained upon the relatively small section of the filter paper surface, which is never absolutely uniform. Considering an extreme case, the tar particles—larger than those present in the cell—may fall one upon the other to extinction of the light in that one spot. Long before such a state is reached the density will fail to increase proportionately with the weight of tar. For comparative purposes it is desirable to secure approximately the same density in each determination, and check the weight of tar per unit area for that density, averaging it over fairly narrow limits.

As an example of an estimation the following figures are given:— $A=2$ sq. cm., $D=0.93$, $T=0.00145$ gm. per sq. cm., $V_g=3819$ c.c.

Tar fog $= 2 \times 0.93 \times 0.00145 \div 0.003819 = 0.70$ gm. per cubic metre $= 0.70 \times 0.436 = 0.30$ grain per cubic foot.

Interesting results have been obtained upon gas streams passing through various manufacturing plants.

Coal gas.	Grains per cubic foot.	Grms. per cubic metre.
A. Outlet condensers following seal in hydraulic mains	30	68
B. Outlet condensers following part sealed and part dry mains with retort house governors	15	34
C. Outlet P and A tar extractors following A	0.25	0.57
D. Outlet rotary exhausters following dry mains and condensers	8	18.3
E. Outlet rotary exhausters following B	6	13.7
F. Outlet turbo exhausters following B	0.6	1.37
G. Outlet Livesey washers following D	0.6	1.37
H. Outlet P and A tar extractors following E	0.17	0.39
I. Outlet P and A tar extractors following F	0.14	0.32
J. Outlet ammonia washers or scrubbers horizontal revolving type following G	0.4	0.9
Water-gas, partly carburetted.		
K. Outlet rotary exhausters following relief holder	2.3	5.2
L. Outlet Crossley tar extractor following K	0.17	0.39

It will be observed that retort house governors have an appreciable effect on the tar fog. The rotary exhausters remove a fair proportion of the remainder. Turbo exhausters reduce the amount to as low a figure as Livesey washers following

rotary exhausters. "P. & A." machines carry the removal to finer limits; the fact to observe is the relatively small difference in the outlet fog compared with a wide range at the inlet. Obviously efficiency should not be based upon the percentage removed. At one works where the A+C combination is used there is trouble with the "P. & A." machines making up; no trouble is experienced with the A+C or F combination; overloading may account for the difficulty.

Accuracy of the method.

It was not expected primarily that the method would yield absolute figures for tar fog with great accuracy. A short experience proves that if we take the densities of the stain per unit volume of gas, the figure is very constant for any given gas stream. Individual determinations reproduce the figure time after time if the variation of density is not too great. It has also been found that the quantity passing similar points in different works, calculated to an absolute amount from the stain readings, is in agreement, despite the fact that the densities of the individual tars to red light differ materially. Whether the method by which the density of the tar is ascertained is perfectly valid or not has not been settled by a direct weighing of the tar fog extracted from the gas, in view of the many difficulties, but the agreement just quoted suggests that it is. Contrasting the filtration and actual weighing of the tar with the method proposed, the former must give low results because of evaporation of the constituents of lower boiling point. With the second it is highly probable that evaporation will not affect the density to light since the colouring matter with the free carbon remains behind.

DISCUSSION.

The CHAIRMAN said that he had himself attempted to face the difficulties with which the author had dealt so ingeniously. He endorsed all that had been said in the paper as to the difficulty of getting a really satisfactory determination of tar fog by direct weighing. In order to obtain a sample some form of conveying tube must be inserted in the gas main and that obviously would disturb the stream lines. Moreover the impinging of tar particles on the sides of the tube resulted in their aggregation and elimination, for they were liquid and not gaseous. A similar difficulty was encountered with ammonia, which tended to elimination by solution. He asked Mr. Edwards if the temperature fell on the way to the filter-paper, because that seemed possible and would interfere with accuracy. The main difficulty in making the method more than approximate was that although dispersion in the comparison cell made every particle capable of exercising its quenching effect on light, that was by no means the case with the filter-paper, where particles might lie one behind the other. The paper showed that the difficulty had been recognised, but a much more considerable range of experiments seemed advisable for determining how far so convenient a method was also reliable. Had the results, showing that the effect of a turbo-exhauster was equivalent with regard to tar fog to that of a rotary exhauster followed by a Livesey washer, been determined by a number of experiments?

Mr. B. A. BURRELL said that the author was to be congratulated on his application of a system used in pure photography to the solution of a difficult problem connected with industrial chemistry. He had found that the various batches of filter paper were by no means uniform and he asked whether this had any effect on the opacity and therefore upon the estimation. Was it necessary to use a standard paper? Also had any attempt been made to use a Lovibond tinto-

meter, and if so could the Lovibond units be converted into Hurter and Driffield units or *vice versa*?

Mr. G. L. MOSS asked if the author had made any estimation of tar fog before and after the benzol scrubbers, and also if the tabulated results from the P. & A. extractors had been obtained under pressure or suction, or some under one and some the other?

Mr. JAMES MILLER asked if the author had tried the use of a soluble organic medium instead of a filter paper—a layer of naphthalene, for instance, to be afterwards dissolved. He thought this would overcome the difficulty suggested by the Chairman with regard to the filter paper.

Mr. GEORGE DOUGILL confirmed what had been said with regard to the turbo-exhauster; he could guarantee its efficiency as a tar extractor.

The CHAIRMAN: In your experience does it carry it as far as the Livesey washer?

Mr. DOUGILL replied that that would be very difficult to say from works observation, but the gas at the Livesey washer was very clean after a turbo-exhauster.

Mr. H. J. HODSMAN asked if the amount of tar fog found did not depend on the point in the cross section of the main from which the sample was drawn, and whether Mr. Edwards' experiments bore on the point. Had the effect of sampling at a bend been compared with sampling from a straight length of main?

Mr. A. WOODMANSEY asked if it were feasible to base a method on direct observation through a column of gas in one of the mains. Some arrangement (*e.g.*, a current of fog-free gas) would be necessary for keeping the glasses clean.

Mr. EDWARDS, in replying as to the temperature of the gas affecting the results, said that all his experiments had been made with cold gas, *i.e.*, with gas not differing by more than 20° or 30° F. from the temperature of the surrounding air. If the metal instrument were allowed to remain in contact with the main long enough there might be some effect, but if the sampling were carried out in a few seconds he did not think there was any deposition of tar from the state of vapour on the filter paper. He had had determinations made on several days on which the temperature of the gas had not varied, while the temperature of the air had been 20° to 30° F. lower, but on every occasion he had obtained the same results at the same point, serving to show that there had been no condensation from the state of vapour. Moreover, the nature of tar fog rendered it very improbable that there would be any such action. It was produced in the retort, and was really free carbon, containing small proportions of the oils, and if it did take up more of these it could only be to a small extent. It was present right up to the Livesey washer, from 6 grains per cubic foot up to, say, 30. He intended to make determinations with hot gas if he could find a gas that contained little enough fog. With reference to the superposition of tar particles on the filter paper not giving comparative results with tar suspended in liquid in a cell, that was of course the crux of the question, and he had not been able to satisfy himself on this point. Regarding the question as to turbo-exhauster results in comparison with rotary exhausters and Livesey washers, he said that he had made perhaps two dozen estimations and they had always come out within 0.1. In reply to Mr. Burrell, he said that different qualities of filter paper were difficult to get, and he had only used one variety. The tintometer was probably a fairly suitable appliance, but not so handy as the density meter. He had not made any determinations before and after the washing

of the gas with oil for benzol. The results as regarded the P. & A. extractor were under pressure: he had not been able to determine whether there was greater efficiency under vacuum. Efficiency was somewhat difficult to define, and one must not take the quantity of tar inside the machine and regard the percentage extracted as a test of efficiency. This was shown by the combination of "A" and "C" in the table of results compared with "E" and "H." The turbo-exhauster was most efficient considering that it was really used for quite a different purpose. As to the position in the main from which it was best to take samples of gas, he had obtained his samples at the periphery. Very different results had been obtained at points facing the gas system and at right angles to it, and anything like the latter method must be avoided. Mr. Miller's suggestion as to the use of naphthalene instead of a filter paper was a very good one if it could be well worked out. It had also been suggested that if tar fog was present in sufficient quantity its density to light could be observed directly by diverting a small stream of the gas from the main stream, but he was afraid that was impracticable.

NOTE UPON APPARATUS FOR THE DETERMINATION OF BOILING POINTS.

BY ALFRED EDWARDS.

Commercial apparatus for the distillation and fractionation of liquids fails to provide for the total immersion of the thermometer stem, with the result that corrections must be applied for the unheated column of mercury. Boiling-point determinations have usually been made under the same conditions; the aim in designing the apparatus used has been to reduce its bulk.

It is desirable to use thermometers under the same conditions of immersion as were adopted when they were made, or as checked by the National

Physical Laboratory. Advantage may then be taken of the corrections without prior calculations for differing stem immersion.

Extended use of the boiling point method for the estimation of benzene and toluene in commercial mixtures (this J., May 31, 1916) and for the control of stills for rectification, emphasises the need for a modified boiling point apparatus, and a still-head has been devised to replace the apparatus described.

An inner tube, A (Fig. 1), about 48 cm. long and 13 to 14 mm. external diameter, is supported by a ring of cork in an outer tube, B, of 16 to 17 mm. bore. The inner tube has a hole blown in the side near the top and projects above and below the outer tube. The outer tube has a side limb, C, of 7 to 8 mm. bore, fused on 38 to 40 cm. from the top. C is bent upwards to form a reflux condenser, the effective length of which is 10 to 15 cm.; the water jacket has a diameter of 16 to 17 mm. Wide-mouthed flasks are attached to B by corks. The vapour rises in A, passes over the thermometer stem, issues by the hole at the top, and descends between A and B, being finally condensed in C and returned to the flask. The return of liquid tends to seal the space between A and B and secure a regular stream of vapour upwards through A. Instead of a cork joint a fused one may be used, as in Fig. 2, or the inner tube may be expanded at the top and supported upon a contraction of the outer tube, as in Fig. 3. The inner tube may be bulbed at the bottom, as in Fig. 4, or the outer contracted, as in Fig. 5, if the sizes of the tubing available allow too much space between them at this point.

The advantages of this apparatus are:—Full immersion of the thermometer stem. The inner current of vapour is protected from draughts by a jacket of vapour. Condensed liquid is returned to the flask below the bulb of the thermometer. Possibilities of superheated vapours are remote. Temperature is maintained steady without fluctuation and without shielding from draughts.

DISCUSSION.

The CHAIRMAN said that Mr. Edwards' use of the term "immersion" avoided an ambiguity which undoubtedly existed at the present time as to the meaning of "exposed" stem. He (the Chairman) had always spoken of the correction for "exposed" stem, meaning thereby the stem exposed to the air, but Spielmann and Jones (this J., 1917, 489) used the term in exactly the opposite sense as meaning the stem exposed to vapour; there was no agreement among chemists or in the literature on the point. Did Mr. Edwards use the jacketing principle in testing liquids which had to be evaporated to dryness?

Mr. H. J. HODSMAN said that if one were determining the boiling point of a mixture, probably a considerable amount of the liquid might be in the upper part of the apparatus, and might conceivably affect the experiment. How far was this a possible source of error?

Mr. EDWARDS, in reply, said that in all apparatus in which total immersion was aimed at, there must be a large vapour phase compared with the liquid phase, and the only way to counteract the effects one had in mind was to use plenty of the liquid. It was possible to turn down the condenser and use it as an ordinary still-head, but that was of no advantage if the neck of the flask were long enough to immerse the thermometer completely, as advised by Prof. Young in his book, "Fractional Distillation."

DR. T. H. BUTLER IN THE CHAIR.

NOTE ON A CURIOUS CASE OF CONDENSER TUBE CORROSION.

BY J. KEWLEY.

The condenser which exhibited the curious type of corrosion explained below was installed in March, 1915, for the purpose of cooling warm fresh water. It was of the ordinary marine type, with tubes of British Admiralty specification, and mild steel tube plates. The body of the condenser was of cast iron. The tubes were fitted into the tube plates by means of wooden ferrules. The metal of the tubes gave on analysis:—Cu 70.68%, Zn 28.81, Sn 0.17, Pb 0.18, Fe 0.20%. The fresh water circulated round the tubes, and brackish dock water circulated through them. The brackish water which caused the corrosion showed on analysis:—NaCl 1348.4 grains per gallon, K_2SO_4 16.9, $CaSO_4$ 36.0, $MgSO_4$ 116.7, $MgCl_2$ 147.5, $MgCO_3$ 1.1 grs. per gall. The fresh water entered at a temperature of about 50° to 60° C., emerging at about 25° C. The range of temperature was thus comparatively small.

After working for four months, the condenser appeared to be leaking badly, and when it was opened up very considerable corrosion had taken place. This was, with very rare exceptions, entirely confined to the ends of the tubes. The corrosion was, moreover, confined to a distance of not more than two inches from the end of the tube, and was confined entirely to the end of the tube at which the brackish water entered. The rest of the tube and the outlet ends were in perfect condition, and showed no trace of corrosion whatever. Further, the corrosion was much more pronounced in the bottom tubes of each of the three compartments, and the number of tubes which had to be replaced was greatest in the lowest compartment, and least in the top compartment. As the hot fresh water entered at the top and the cold brackish water at the bottom, the maximum corrosion took place at the point where the difference of temperature was least.

After replacing the worst tubes, the condenser was again boxed up, and after a further three months was again opened, and exactly the same state of affairs found as on the previous occasion. The difficulty was, however, overcome in a very simple manner. The bad ends of the corroded tubes were cut off and these tubes were lengthened by the addition of nine inches of similar tube joined on by a sleeve made of the same material but of larger diameter, the joint being sweated over with solder. All the tubes were so treated and put back in the condenser with nine inches of their length projecting at the outlet ends. After a run of three months the condenser was opened, and the tubes all knocked through a distance of two inches, so that the badly corroded inlet ends projected. During the next three months a further two inches was corroded away, and the process repeated. The tedious and expensive process of re-tubing the condenser was thus necessary very much less often. As the tube became eaten away at one end it was lengthened at the other.

It is of great interest to note that another condenser, working under the same conditions, showed no signs of corrosion over a period of two years. In this case, however, the tubes were

made of "Nergandin alloy" (Cu 70, Zn 28, Pb 2%), and tube plates and ferrules of Muntz metal.

DR. CHARLES A. KEANE IN THE CHAIR.

CORROSION OF LEAD ROOFING.

BY J. S. S. BRAME.

Two interesting cases of corrosion of lead sheet used for roofing have been investigated.

In the first case cast lead sheets had been in position on a wood foundation for a long period. I am unfortunately unable to give the number of years as no record of the date of roofing has been kept. It was found that in places serious corrosion had occurred, the lead being in some instances perforated. Beneath the corroded parts thick crusts of white deposit were found, and these on analysis proved to have a composition well within the range of commercial white lead. The following are the results for two samples:—

	Sample A.	Sample B.	Required for $2PbCO_3$, $Pb(HO)_2$.
	%	%	%
Lead monoxide (PbO)	85.60	84.10	86.32
Carbon dioxide.....	11.50	11.70	11.36
Combined water.....	2.15	2.05	2.32
Organic and other constituents (diff.)	0.75	2.15	—
	100.00	100.00	100.00

Examination showed that the lead had only corroded where in contact with oak beams; the other portion of the wood-work consisted of pine. In Bloxam's "Chemistry" it is stated that "the lead of old coffins is often found converted into a white earthy mass of basic carbonate, with a very thin film of lead inside it." It would be interesting to know whether this applies to lead in contact with other woods than oak. Miller, who did much valuable work on the action of water on lead, says "green oak wood, from the quantity of acetic acid which it contains, should not be used in contact with lead for building purposes." I have been told that in erecting sulphuric acid chambers it was recognised that oak and lead should not come in contact, but on inquiry I find that corrosion of lead under these circumstances is not generally realised, and therefore venture to record these observations.

The second case of lead corrosion was more remarkable and occurred where the metal had been laid on a coke-breeze concrete. Here patches of a thick crust of a red substance had accumulated between the lead and the concrete, and in places the lead was eaten through. In this case the action had been somewhat rapid, the building being only some 15 years old, when a leaky roof revealed the serious corrosion which had been going on.

The corrosion product had the following ultimate composition:—Pb 91.64%, Fe 0.081, O 7.450, organic matter, carbonates, etc. (diff.), 0.826%. The theoretical amount of oxygen required to form

PbO from the lead present is 6.57%, so that there is excess oxygen equal to 0.88%. From this result, and from the red colour of the corrosion product, it is evident that either lead sesquioxide (Pb_2O_3) or red lead (Pb_3O_4) is present in addition to the lead protoxide (PbO) which constitutes the bulk of the material. From the ultimate analysis the following alternative approximations of the probable composition of the material (exclusive of the minor constituents, Fe_2O_3 , CO_2 , etc.) may be made:—

Lead protoxide (PbO)	90%	or	86%
Lead sesquioxide (Pb_2O_3)	9%	Red lead (Pb_3O_4)	13%

It is usual to regard both the Pb_2O_3 and Pb_3O_4 as composed of protoxide (PbO) and dioxide (PbO_2), and confirmation of the presence of lead dioxide is afforded by the evolution of some chlorine when the material is distilled with hydrochloric acid.

The coke-breeze concrete consisted of about 8 parts of coke-breeze and 1 part of Portland cement, the latter in the set condition being usually regarded as containing a certain proportion of calcium hydroxide, and the action was probably due to this free lime, which, in the presence of moisture, has been stated to form hydrated lead oxides with the metal. In some of the older textbooks it is stated that lead should not be placed in contact with mortar, plaster, etc., on account of corrosion, but I have been unable to trace any reference to the character of this action. Certainly the production of an oxide higher than PbO is remarkable.

DISCUSSION.

Dr. S. MIALl said that it was unfortunate that the true early history of both these examples was not available. As regards the first instance, he was very doubtful whether there was sufficient acetic acid in ordinary oak to act upon sheet lead placed in contact with it. He did not believe there would be any greater corrosion with dry oak than with dry elm or any other wood. The second instance of corrosion was remarkable and difficult to understand. Was it possible that the circumstances in which the sheet lead was placed were such that there was any formation of calcium plumbite which might afterwards form calcium plumbate? This would be readily attacked and might form a certain amount of peroxide or red lead.

Mr. G. NEVILL HUNTLY, referring to the second case, said that some years ago several examples of the corrosion of leaden pipes by mortar were shown him. The corrosion products were white. It appeared probable that a calcium plumbate was formed, but it could not be definitely proved. It was, however, a well-established tradition among plumbers not to allow lead pipes to come in contact with lime or mortar.

Mr. ARNOLD PHILIP pointed out that electric cable companies always stated that lead-covered cables must not be brought into contact with Portland cement. He had seen several cases of corrosion of lead-covered cables from the neglect of this precaution but he did not understand their origin.

Mr. WALTER F. REID said that the corrosive action of Portland cement on lead was well known but the cause of it was not known. Alkalis were present and a small percentage might cause considerable action on the lead. Portland cement made in the Thames valley was rich in alkalis and it would be very unsafe to put lead in direct contact with it, especially with a substance like coke, which contained a great deal of sulphur. It was also known that breeze contained rather more sulphur than coke and some action might be due to the sulphur, whether on the lead or other ingredients he was unable to say, because it was

not quite certain in what form the sulphur was present in the coke. The condensation of water he thought had a great deal to do with the corrosion of lead in contact with wood. He had noticed that where galvanised iron was fastened to wood there was condensation of moisture on the other side of the iron, and with continually recurring fog in such a climate as ours corrosion might be started.

Prof. BRAME, replying to Dr. Miall, said that the building from which the first instance of corrosion had been taken was over 200 years old and probably lead had been there the whole time. There was no record of it having been re-roofed. There was possibly a good deal in whether the wood was green or properly seasoned. There was something about oak which gave this corrosive effect; for instance, iron nails used in oak fencing were affected invariably. It was the red colour which he considered the most remarkable part in the second instance he had brought forward. He had seen pipes taken out where there was white corrosion but never coloured like that. It had been suggested that the sulphur in coke-breeze might cause the corrosion, but there was nothing more than a trace of sulphur in the corroded material. Dr. Miall's suggestion as to the action of the lime forming a plumbite or plumbate was probably the real explanation of the initial action in the second instance.

THE ACTION OF RAIN WATER ON A PORTLAND STONE.

BY J. S. S. BRAME.

It is well recognised that certain limestone buildings in large cities have suffered considerably from weathering, but beyond the general statement that rain water charged with acids, such as sulphurous acid, attacks carbonated stones with some rapidity, converting the carbonates into sulphates, I have been unable to trace any reference to the actual changes which occur.

My attention was directed to a thick black crust beneath the wide overhanging cornice of a building of Portland stone some 200 years old. The crust was so thick that it had almost completely blocked up the fine carving on the underside of the cornice. It was decided to remove this crust and samples were obtained for analysis.

The crust was almost black through included organic matter (soot, etc.). The air-dried material gave the following results:—Moisture 1.79%, organic matter 23.34%, mineral matter 74.85%.

Comparison of the composition of the stone (which apparently in the part taken had been little altered, as it consisted almost entirely of carbonates) with the mineral constituents of the crust is given below:—

	Lime-stone.	Inorganic constituents of crust:		
		Sol. in HCl.	Insol. in HCl.	Total.
	%	%	%	%
Lime (CaO)	52.71	25.10	7.71	32.81
Magnesia (MgO)	1.33	2.11	0.34	2.45
Iron and aluminium oxides (Fe_2O_3 , Al_2O_3)	0.38	1.98	1.28	3.26
Sulphuric anhydride (SO_3)	1.25	38.25	11.16	49.41
Carbon dioxide (CO_2) ..	41.32	2.07	—	2.07
Silica (SiO_2)	2.72	—	9.94	9.94
Organic and loss	0.29	—	—	—
	100.00	69.51	30.43	99.94

It is clear that the crust consists mainly of calcium sulphate, the next main constituent being silica. In the portion insoluble in hydrochloric acid a large quantity of fine needle-shaped crystals was found, these being presumably calcium sulphate. The acid rain water collecting on the upper flat side of the cornice, which was some 2 ft. 6 ins. wide, had slowly percolated through the stone, decomposing the calcium carbonate with formation of the sulphate, which was deposited by evaporation on the underside, thus bearing out the correctness of the general statement of the action of rain water containing traces of oxides of sulphur, resulting from the coal consumed in large towns.

Particular interest attaches, however, to the high percentage of silica in the crust. In the part insoluble in hydrochloric acid, the bases other than lime (which is entirely accounted for as sulphate) are in very small amount, and the silica is practically wholly in an uncombined condition. Of the total silica (2.72%) present in the original stone, about 17% was obtained in the soluble form on treating 50 grms. of the limestone with hydrochloric acid. It would appear then that the slightly acid rain water percolating slowly through the stone had brought about slow decomposition of certain silicates and the silica was left uncombined in admixture with the calcium sulphate, which formed over 80% of the crust.

THE RAPID ESTIMATION OF PYRIDINE BASES IN AMMONIA AND ITS SALTS.

BY T. F. HARVEY AND C. F. SPARKS.

The detection of pyridine or pyridine bases in ammonia solutions and in ammonium carbonate is frequently carried out by merely neutralising the greater part of the ammonia, and noting the odour of the slightly alkaline liquid. Some idea of the amount of the impurity may be formed from the intensity of the pyridine odour, but such a method can only serve for very rough purposes, or in the case when the ammonia under examination happens to be practically free from pyridine. No rapid and convenient method by which small quantities of pyridine or pyridine bases can be accurately estimated has been published, so far as we are aware.

In aqueous solution, François (*Comptes rend.*, 1903, 137, 324) this J., 1903, 1017) estimates quantities of about 100 mgrms. by preparing the aurichloride and igniting, while Labat employs *N*/20 bromine solution for the titration of decided quantities of pyridine, but the method is purely empirical and insensitive.

Pennock and Morlon (*J. Amer. Chem. Soc.*, 1902, 24, 385) propose to neutralise 100 c.c. of ammonia solution with sulphuric acid, using methyl orange as indicator, and distil a portion of the resulting liquid. The distillate is cooled and precipitated with a slight excess of mercuric chloride, which removes all the ammonia as NH_2HgCl . The solution is filtered, and the pyridine titrated with *N*/10 acid in presence of methyl orange.

Milbauer and Staněk (*Z. anal. Chem.*, 1904, 43, 215; this J., 1904, 563) dilute 100 or 200 c.c. of ammonia with water and evaporate with an excess of dilute sulphuric acid nearly to dryness. The residual liquid is mechanically shaken with freshly prepared sodium bicarbonate and ether two or three times, the united ethereal extracts being shaken out with *N*/10 sulphuric acid and the excess of acid titrated in the presence of Patent Blue and sodium chloride. The method is said to be accurate.

Houghton (*J. Ind. Eng. Chem.*, 1909, 1, 698; this J., 1909, 1195), has described a method in which, after a preliminary distillation from slightly alkaline solution, the ammonia is destroyed by hypobromite, the unchanged pyridine being distilled into *N*/10 acid and titrated.

Other modifications involving distillation have been described, but none of the methods we have found is rapid, and the accuracy of some is very doubtful.

The method we have devised depends on the rapid and complete precipitation of pyridine or pyridine bases from an acid solution of the sample, which may be ammonia, ammonium carbonate, or other ammonium salt, as periodides, and subsequent titration of the sulphate of the bases with *N*/10 alkali. The use of iodine as a delicate precipitant for organic bases is well known, and has been used by Staněk (*Z. physiol. Chem.*, 1906, 47, 38) for the determination of choline and betaine. Choline is stated to form an enneaiodide which soon becomes crystalline, forming shining green rhomboidal leaflets, and the limit of precipitation for choline is said to be 1 part in two million. From solution in *N*/2 sulphuric acid we find that iodine will precipitate pyridine at a dilution of about 1 part in 20,000. At a dilution of about 1 part in 50,000, there is practically no precipitate formed. This is not sufficiently delicate for the purpose, but we find that the sensitiveness is greatly increased by the addition of sodium chloride to the solution. The salting-out action of sodium chloride upon atropine periodide was already known to one of the authors, and was discovered by him in conjunction with A. D. Powell during a previous investigation. In the presence of a sufficient quantity of sodium chloride, this action is so marked that 1 mgrm. of pyridine in 200 c.c. of *N*/2 acid (1 in 200,000) appears to be completely precipitated. It should be noted that the effect of working in strongly saline solution is in this case to cause precipitation of iodine itself even in the absence of organic base, and to this fact may perhaps be due the very complete removal of the base from solution. The periodides obtained under these conditions are almost certainly contaminated with co-precipitated iodine, which precludes the use of an iodometric method for their estimation. In the few cases where we have determined the iodine content of the precipitate, it has corresponded to something like 18 atoms of iodine per molecule of base. After precipitation and washing, the periodides are treated with a small excess of thiosulphate solution and then titrated, first in presence of methyl orange (methyl red is not available) and then with phenolphthalein, the differential titration being the basis of calculation.

The solutions required and the details of the method are as follows:—

Special iodine solution. Iodine, 13 grms.; potassium iodide, 13 grms. (more must not be used); water, to 100 c.c.

Special wash solution. 10-*N* sulphuric acid, 10 c.c.; water, 190 c.c.; special iodine solution, 10 c.c. Allow to stand overnight and filter out any precipitated iodine.

Sulphuric acid of about 10-*N* strength.

The indicator solutions actually used in the experiments were prepared as follows:—

Methyl orange solution. containing about 0.2 grm. of methyl orange in 1000 parts of water.

Phenolphthalein solution. containing about 1 part of phenolphthalein in 500 parts of 50% alcohol.

A stoppered separator capable of holding 300 c.c. or more, and having a tubulure above the tap that can be easily plugged with a small pledget of cotton wool, is used. This is dried internally or merely rinsed with strong alcohol and then

plugged with a small piece ($\frac{1}{2}$ inch square should suffice) of cotton wool to serve as a filter. A conical ended glass rod answers well for inserting the plug, which should then be pressed down moderately, so that water will pass easily in a thin stream under the pressure obtainable from a small indiarubber hand-bellows. The tap is then closed, and 50 c.c. of water placed in the separator, followed by 50 c.c. of the ammonia to be tested (of sp. gr. about 0.885). 100 c.c. of 10-N sulphuric acid is then gradually added, the separator being cooled under the tap. The liquid then contains about 2.5% w/v of free sulphuric acid. 50 grms. of clean sodium chloride is next added, and when solution is complete and the contents are cold, 10 c.c. of the special iodine solution is run in. The separator is then shaken for some minutes till the precipitate aggregates and leaves the liquid fairly clear. After standing for about 15 minutes the liquid is forced through the cotton wool filter by means of an indiarubber hand-bellows, the tap being closed just before air reaches the plug. This filtration usually occupies about 5 minutes or slightly more. Twenty c.c. of the special wash solution is then added, and after the separator has been gently rotated, is forced out through the filter as before, but completely. A slight excess of saturated thiosulphate solution is then gradually added to the separator, with shaking, till all is colourless, the cotton wool being displaced either by shaking, or if necessary by means of a wire. If desired the excess of thiosulphate may be removed carefully by means of N/10 iodine solution, but this is not necessary unless too great an excess has been added. The total volume is now made up to about 20 c.c., two drops of methyl orange are added, and neutrality carefully established with N/1 sodium hydroxide, finishing with N/10 sodium hydroxide. 0.5 c.c. of phenolphthalein solution is then added and the pyridine sulphate titrated with N/10 sodium hydroxide (1 c.c. = 0.0079 gm. of pyridine or of pyridine bases calculated as pyridine).

It will be seen from the figures given below that although the quantities of base used in the experiments were small, varying from 5 to 50 mgrms., yet a considerable degree of accuracy was obtained. It is of course necessary if precise results are desired to exercise some care in the choice of the two end points. The correct end point in the methyl orange titration is attained when the colour changes from red to orange—one more drop should then produce the yellow colour. The phenolphthalein end point is a sharp one but is not permanent, and the first decided red colour (which lasts for about half a minute) should be taken. We have in no case found the small excess of thiosulphate used to interfere with the titrations, but as stated it can be removed if desired. It is possible to use glass wool well packed as a filtering medium and filtration is more rapid, but in that case a rubber stopper will be found necessary and the filter is much more difficult to displace from its position. The quantity of sulphuric acid used is intended to leave the solution about half normal in free acid, but considerable variation in this respect does not appear to influence the result. As will be seen, we have varied the acid between N/4 and N/1 and obtained the same figure. Larger quantities than 50 mgrms. of base have not been tried, but probably the method is capable of extension, using proportionately larger quantities of iodine solution.

Experimental.

The first series of experiments was made using a dilute solution of crude pyridine bases (a)—the latter had sp. gr. 0.983 and 95% distilled between 90° and 142° C. Titration to methyl orange gave 82% and to phenolphthalein 81.7% calculated as pyridine.

Pyridine bases taken.	c.c. N/10 soda to phenolphthalein after pptn. from 200 c.c. liquid.	% recovered base calculated as pyridine.
gm.		
0.005	0.53	85.5

0.02	2.1	82.9
0.03	3.15	82.9
0.04	4.2	82.9
0.05	5.3	83.5
	Theory =	81.7

Another sample of crude pyridine bases (b) was used; this distilled at 100°–140° C. and titrated to methyl orange as 85% and to phenolphthalein as 84.8% pyridine.

Pyridine bases taken.	c.c. N/10 soda to phenolphthalein after pptn. from 200 c.c. liquid.	% recovered base calculated as pyridine.
gm.		
0.005	0.52	82.1
0.01	1.1	86.9
0.02	2.2	86.9
0.03	3.18	83.7
0.04	4.2	82.9
0.05	5.3	85.5
	Theory =	84.8

A sample of ammonia was then taken which had been found to contain 0.0103, 0.0103% of bases calculated as pyridine. Pyridine base (a) was added in amount corresponding to 0.02% pyridine. The total pyridine found was 0.0302% (theory 0.0303%). To another sample of ammonia containing 0.022%, 0.023% of pyridine, was added pyridine base (b) equivalent to 0.034% pyridine. The total base recovered was then 0.055% (theory 0.056%).

A series of experiments was carried out with a sample of nearly pure pyridine of sp. gr. 0.986, which titrated 95.9% to methyl orange and 96.1% to phenolphthalein.

Pyridine bases taken.	c.c. N/10 soda to phenolphthalein after pptn. from 200 c.c. liquid.	% recovered base calculated as pyridine.

0.02	2.45	96.8
0.03	3.64	95.9
0.04	4.85	95.8
0.05	6.15	97.2
	Theory =	96.1

Some experiments were then made with varying quantities of acid, using the same sample of ammonia throughout.

Normality of acid before pptn.	% Pyridine found.
Approximately N/4	0.0103
" N/2	0.0103
" 3N/4	0.0103
" N/1	0.0103

Two further samples of strong ammonia solution were examined, and gave respectively 0.028% pyridine (four estimations) and 0.01% pyridine.

An experiment in which the salt was purposely omitted gave only 0.0087% pyridine instead of 0.028%, showing that the ammonium sulphate formed did not of itself ensure precipitation of the pyridine.

Some samples of ammonium salts were tested with the following results:—

	Pyridine %
Ammonium carbonate	0.024
" chloride	0.008
" sulphate	0.010
" nitrate	0.013

Finally, in an attempt to prepare a solution of ammonium sulphate entirely free from pyridine, 100 c.c. of ammonia containing 0.028% pyridine was diluted, neutralised, and distilled from slightly alkaline solution as recommended by Houghton; 25% was distilled and the two portions were examined. The pyridine was then found to be distributed as follows:—

	Pyridine %
In the distillate	0.0005
In the residual liquid.....	0.0175
Total	0.0270

The retention of about two-thirds of the pyridine in the distilling flask seems to throw considerable doubt on methods involving separation by distillation.

The authors are indebted to Messrs. T. Morson and Son, Ltd., in whose laboratories this investigation was made.

DISCUSSION.

The CHAIRMAN said that the authors were to be congratulated upon having devised a means of separating the pyridine previous to its actual estimation. Such a method of work was likely to give the most satisfactory results. He suggested that the authors might find methyl iodide an effective reagent for getting the ammonia free from pyridine as the pyridinium iodide formed was a very characteristic compound.

Mr. A. CHASTON CHAPMAN said that he had on various occasions found himself confronted with the problem of determining traces of pyridine both in ammonia solution and in liquid ammonia. In the latter case its presence was particularly objectionable, owing apparently to its injurious effect on certain parts of refrigerating machinery. The method he had adopted was to concentrate the pyridine in the manner referred to by the authors and then to titrate the pyridine and residual ammonia, using different indicators. He had never felt very happy about the results but the method was, so far as he was aware, the best available. Pyridine formed a good many more or less insoluble compounds with metallic salts, but such experiments as he had made were not very successful, owing to the need for concentrating the pyridine and to the very small quantities of that substance usually present.

Mr. HARVEY, in reply, said that they had not endeavoured to obtain ammonia free from pyridine by the agency of methyl iodide. The accuracy of the figures had surprised both Mr. Sparks and himself in view of the very small quantities worked upon. The periodides were precipitated very completely in the presence of sodium chloride, but in the absence of the latter only partially. They had not isolated pyridine periodide, but this had previously been done by Dafert, who gave it the formula $C_5H_5HI_3$.

MR. H. PEILE IN THE CHAIR.

NOTES ON TESTING HARDNESS OF METALS.

BY J. W. CRAGGS.

In the mechanical testing of metals the determination of hardness is of considerable importance, because of the comparative reliability of the results and the ease with which it may be carried

out. But the endeavour of the engineer and metallurgist to express in values some definite property, useful for their special needs and related to hardness, has caused them to give a meaning to the term not understood or used by mineralogists or laymen. To these it means simply that property which denotes resistance to penetration; while to the engineer it may mean abrasive, cutting, elastic, or tensile hardness. It is quite right that the engineer should endeavour to find simple tests that shall indicate to him the behaviour, in actual use, of the material under consideration, but he causes confusion if he groups all the different properties which he so uses under a term, such as hardness, to which a definite meaning is already appropriated. The object of these notes is to discuss the right use and application of the methods at our disposal for testing hardness. Many of the tests are of great importance in indicating specific properties, and efforts should be made strictly to limit the use of these tests to those instances where practice has upheld their utility. It would then naturally follow that instead of the results being loosely termed "Hardness numbers" they would be given a nomenclature indicating the property determined.

The methods used may all be grouped as:—

- (1) Indentation tests, whether (a) gradual, or (b) sudden.
- (2) Abrasion or scratch tests.

Though Wahlberg extends this classification to a third, in which he places Foepppl's method, the latter should rightly be placed under indentation tests. These depend on the permanent distortion of the material, under pressure, by means of a hard steel ball, cone, or knife edge; and the abrasion or scratch tests on the material removed from the surface during sliding contact with another body of such superior hardness that its surface remains unimpaired by the action.

As the tests that have been introduced are so numerous it is impossible to note more than two or three in each group, and attention will therefore be given to the following:—

- (1) *Indentation tests.* (a) Brinell test. (b) Shore's scleroscope. (c) Pellin test.

- (2) *Abrasion or scratch tests.* (a) Turner's sclerometer. (b) Martens' sclerometer. (c) Saniter's abrasion test.

*Brinell test.** Brinell's machine is most widely used to-day. In this method a hardened steel ball, capable of resisting deformation, is pressed into the face of the metal to be tested. The spherical area of the indentation being calculated, and the applied pressure being known, the stress per unit area may be determined, thereby giving the hardness number. The results are, within limits, independent of the size of the ball and the pressure applied. The sample for test need only be small, and the actual operation occupies two or three minutes to perform. Two types are in common use; one of Swedish make known as the Aktiebolaget Alpha—a ball test; and the Martens, in which a conical indentation is produced and the pressure exerted by means of water and not weights as in the former. The Martens machine finds support in that the cones can now be prepared with sufficient accuracy to secure consistent results, and the depth of conical indentation possesses advantages in calculating. In the ball-test a 10 mm. ball is most commonly used with a weight of 3000 kilos, for steels, and 1000 kilos, or even 500 kilos, for brasses and comparatively soft alloys. In investigations of a particular class of

Fig. 1.
Brinell test.

material it is advisable to use the same sized ball and equal pressures throughout where comparisons are being made.

*Shore's scleroscope.** In this instrument a small steel cylinder or "hammer," with a hardened or diamond point, is allowed to fall from a height of about 10 inches upon the polished surface of the metal to be tested. The hardness is measured by the height of the rebound and for this purpose the tube is graduated into 140 divisions so that hardenite gives a reading of approximately 100. It follows that readings exceeding 110 are only given by materials of unusual hardness. One advantage possessed by Shore's scleroscope is its convenience. It is small and may readily be carried for the testing of any sample, large or small. The indentation produced might pass unobserved and could therefore be made on a finished article, for the area of the indenting point is stated to be only $\frac{1}{2500}$ of a square inch. An illustration of the scleroscope is given in the *Journal* for 1915, page 536.

Pellin test. This, at first sight, appears to be a combination of the preceding tests; it is, however, based on the Brinell method and has been designed for the testing of the different metals used for all industrial purposes. It is essentially one in which the indentation is produced by a falling bar of known weight, having at the lower end a steel ball 2.5 mm. in diameter. The apparatus is arranged so that instant release may be obtained by an annular electro-magnet carried by a housing in

Fig. 2.
Pellin test.

which the bar slides freely. When in position for use the bar is retained there by the magnetic attraction of the soft iron collar, fitted to it, to the magnet on the housing. The diameter of indentation may be varied by means of weights placed on the top of the bar or by altering the distance of fall. When the impression has been made its diameter is measured and, knowing the weight used, the hardness number may be calculated.

*Turner's sclerosometer.** By this device a standard scratch is produced on the polished surface of the metal. A weighted diamond point is drawn once forward and once backward, and the hardness number is the weight in grms. required to

Fig. 3.
Turner sclerosometer.

produce the standard scratch. Turner describes this as one just visible to the naked eye as a dark line on a bright reflecting surface, or as a scratch which can just be felt with the edge of a quill when the latter is drawn over the smooth surface at right angles to a series of such scratches made by regularly increasing weights. Of the many forms of sclerosometer it is that most generally used.

Martens' sclerosometer. Here the scratch is varied and the weight is kept constant. The usual load is 20 grms. and the point is stationary, whilst the specimen is drawn backward and forward by a traversing table. The determination is made by a careful measurement of the width of scratch, on the horizontal polished surface, by means of a microscope with micrometer eyepiece, or by photographing the scratch under a known magnification. The hardness number is the reciprocal of the width of the scratch in millimetres.

* Turner. *Proc. Birmingham Phil. Soc.*, 5, Part 2.

*Saniter's test.** Devised particularly for the determination of the wearing property of rail steel, this method attempts a reproduction of the actual stresses encountered in use. The test-

Fig. 4.
Saniter test.

piece is 5 in. long by 0.5 in. diameter and is fixed in a chuck which revolves at 4000 revs. per minute. Near the free end the test-piece rotates by friction the inner ring of a ball bearing which is loaded to produce a pressure equal to 205 lb. at the point of contact. The length of this contact section is $\frac{1}{8}$ in. and the total number of revolutions made by the test-piece 200,000. One test occupies about 50 minutes. The wear number is the ten-thousandth parts of an inch removed from the diameter of the bar during the test. To ensure accuracy Saniter recommends that the test-piece be measured in three places, and also in a plane at right angles, making six measurements in all, the average being taken as the correct number. These are all recorded before as well as after the test, for even in the original test-piece slight irregularities may occur. The smallest wear number represents the least wear, and consequently the best wearing steel. The test-pieces are always taken in a longitudinal direction relative to the actual rail.

Value of the tests in practice.

Confidence in the Brinell method for constructive, ductile materials, as a measure of the tenacity, is now general, as evidenced by its extensive use in engineering practice. It is very easily applied and when used correctly may be said to give definite results. Adopted originally for ordinary carbon steels, its application has been extended to special steels, and to alloys of the non-ferrous type, and if data be collected for each class of material the results can be used with certitude. McWilliam and Barnes† have examined steels of varying carbon content in the presence of 2% chromium and 3% nickel, and also with 0.2% vanadium. In all three types of steel they found the factor for the conversion of the Brinell number to the maximum stress to vary, though the variation was small. Their factors were chrome steels, 0.242; nickel steels, 0.239; and vanadium steels, 0.235. From these it may be observed that where a particular type is being regularly handled the factor may be determined and constancy obtained, whatever the carbon content or physical condition.

Knowledge of the material is an important reservation that one must note in seeking to apply the method. The general application to all alloys—ferrous and non-ferrous—without definite information of the type, involves liability to dis-

crepancies, e.g., with a cast cartridge metal, which is entirely α , the factor is in the neighbourhood of 0.28—0.30; while with a brass of the Muntz metal class, in which there are practically equal portions of α and β , it is from 0.25—0.27, and, in the case of an all β brass, approximates to 0.24—0.25. Such figures, of course, are only directly applicable to the copper-zinc series of alloys. The addition of a third element, say aluminium or manganese, to adjust the structure so as to give a particular type, would necessitate further investigation in the determination of special characteristics even though the micro-structure be identical with that of a pure copper-zinc alloy. With samples in which the structure is so small that numerous grains are included in the impression made by the ball, their different orientation will eliminate variations in the test, but with large grains this is not so. Appreciable disturbance is caused, so that in samples which possess a coarse structure, whether of a simple or complex nature, the character of the impression will depend upon the orientation of the crystal grain on which such an impression is made. Actual determinations made on two adjacent crystal grains gave unsymmetrical impressions of different forms that could not be measured. Similarly with a test on the crystal boundary the irregularities were such as to prohibit any comparison being made. A photograph of such an impression is shown in Fig. 5. We may conclude that metals and alloys possessing a coarse structure will tend to give unreliable results and may even be such as to prevent an approximation being made. This irregularity in the indentation is not usual with all soft or ductile materials, though other workers have had at times a similar difficulty with the ball

Fig. 5.
Large β crystals of Cu-Zn showing irregular Brinell indentation, $\times 15$.

test. It was in this instance probably accentuated by the coarseness of the crystals, resulting in a condition in which slipping within the crystal was more easily induced.

With hard and brittle materials the Brinell test is of much less value. This fact is obvious if one thinks of the determination as giving, in a sense, a measure of the viscosity of the solid, for flow must take place. The indentation due to the pressure by the ball or cone is produced by compression, shearing, and translation along gliding planes. In a ductile body this readily occurs, as seen in photomicrographs Nos. 1 and 2, Fig. 6, in which the elongation of the crystals in an α -brass

* Saniter. Journ. Iron and Steel Inst., 1908, III., p. 73.

† Journ. Iron and Steel Inst., 1915, 91, 125.

is clearly shown, with the presence of numerous slip-bands. With a hard alloy fracture may occur at once or after a short interval, the crack or cracks radiating from the point of test.

Again, in testing hard material cracking may not take place and yet the determination may be unsatisfactory, for the balls, which contain approximately 1% of carbon, 1.5% of chromium, 0.2% of nickel, and are oil-quenched from 800° C., only possess a limited rigidity. When distortion of the ball is observed the impression made by it will not give a true figure. To show the unreliability of tests in which the Brinell number is recorded as 730 to 750, and in some instances still higher, chrome, nickel-chrome, nickel-chrome-vanadium, and high-speed steels were hardened and determinations made. Several balls were tried and in each case there was distinct flattening of the ball. The highest figure recorded was 653. In many instances, as will be noticed below, the maximum reading was 625.

Apart from these limitations, this test may be rendered valueless by careless manipulation, especially in regard to the time factor. Thomas* has shown that differences may be recorded by varying the time of application of the pressure up to 8 or even 10 minutes, when testing mild steel. The differences, however, are only slight after one minute and he therefore urges the adoption of this as the standard time for the test. The thickness of the sample must also be such that stresses set up by the ball are dissipated before penetrating throughout the full depth of the piece. Many experiments led him to declare that 0.38 inch should be the minimum when a normal load of 3000 kilos. is used. If the thickness chanced to be from 0.15 or 0.20 to 0.38 inch the load should be less, say 1000 kilos., for satisfactory results; while an

possible is very small for each annealing, while with others a considerable amount of work can be done. From this fact it may be observed that where large indentations are made through excessive loading, the hardness numbers may be misleading. A standard load should be adopted for each individual class of alloy.

In using the Shore scleroscope some property other than the tenacity is indicated. If in falling the "hammer" produced no indentation a true measure of the elasticity would be given, but in

Fig. 6, No. 2.

*Cartridge metal—Stressed and unstressed.
By Brinell ball, $\times 100$.*

practice this does not occur. Yet the penetration is so small that the result gives usually an approximate measure of the elastic limit. The figures are of great value when the nature and properties of the alloy under examination are familiar; or if a measure of the cold-work that has been applied is desired, for the test exhibits most strongly the "hard worked" or "écroui" condition. Probably this is due to the more rapid increase in the elastic limit than in the maximum stress, when work is applied, for the Brinell number does not increase at the same rate. It is because of this characteristic of the scleroscope test that many investigators find no proportionality between it and the Brinell test.

Generally, in the cast or normal condition a rough comparison of the Brinell and scleroscope numbers may be made by the use of the following factors, which have been calculated from hundreds of tests performed:—

Ordinary carbon steel	Scleroscope No. $\times 6.67 =$ Brinell hardness No.
Nickel and nickel-chrome steels ..	" " $\times 7.0 =$ " " "
Cast iron and bronzes	" " $\times 5.25 =$ " " "
Aluminium and light alloys	" " $\times 6.0 =$ " " "

It must be understood, however, that these factors should not be used carelessly: a knowledge of the physical condition of the metal is essential. In the paper by McWilliams and Barnes, already cited, it is declared that there is no constant factor for the scleroscope and Brinell tests in alloy steels. This conclusion is perhaps the better for scientific purposes, for each test is a measure of different properties. The above factors exhibit the general trend of the results and are only of value if correctly applied.

Experiments made with a view to determining

Fig. 6, No. 1.

*Cartridge metal—Stressed and unstressed.
By Brinell ball, $\times 100$.*

interesting series of tests with thin pieces backed first by hard steel, and secondly by wood, showed that it was essential to support the sample by material as hard as or harder than the test-piece, otherwise the results were variable.

Many apparently strange results may be explained by the differences in the amount of cold-work that will produce "overstrain" in various alloys. With certain of the high tenacity light alloys, for example, the amount of cold-work

* J. Iron and Steel Inst., 1916, I, p. 255.

the difference shown in the hardness by the Brinell, scleroscope, and simple scratch tests on a sample of nickel-chrome steel gave the following interesting results:—

or pass the tool on the figure. The cutting efficiency depends upon the stability of the constitution of the hardened steel over a wide range of temperature and is not related to the Brinell

Quenching medium.	Temp.	Brinell.	Sclero- scope.	File test.	Glass test.	Rose quartz test.
1. Rape oil	800	625	80	No mark.	Scratched with ease.	With difficulty.
2. Cold water	800	625	80	"	"	With great difficulty.
3. Boiling water	800	625	80	"	"	"
4. Contact with cold iron slab	800	625	80	Just bites.	"	With ease.
5. Strong air blast	800	625	77	No mark.	"	With difficulty.
6. Spray of cold water	800	625	77	Great difficulty.	"	"
7. Concentrated sulphuric acid	800	625	74	No mark.	"	"
8. Spray of water; face of sample at 800° C. with core at 600° C.	800	625	75	Great difficulty.	"	Just marks.

The "file hardness" test was made with a new 8-inch dead smooth feather-edged file for each test. The "glass hardness" test was applied so that the edge of the sample was drawn over the face of a piece of highly-polished plate glass. The "quartz" test was made in a similar manner to the file test, with crystals of rose quartz.

These results show no variation in the Brinell numbers and practically none in the scleroscope figures. The former test indicates practically the maximum obtainable by such a test and in each case a new ball was used. The scleroscope test, being an indication of the resilience or elastic hardness, shows slight variations, though test No. 4 is remarkable as exhibiting no change, while the quartz scratched the sample with ease. No doubt the hardness is best measured by resistance to penetration, but the actual value varies according to the mode and rate in which the test is made. Each test has its own definite value, as suggested above, and should be applied accordingly.

Sufficient data have not yet been collected to determine the true value of the Pellin test, and no generalisation can be made with any certainty. The principle on which the test depends, its simplicity, and the rapidity with which it may be carried out, suggest for it an important future. The smaller indentation gives probably an advantage over the Brinell method.

The sclerometer methods mentioned give better values than the above tests of the absolute hardness of the material. But, as Howe has mentioned, considerable difficulty is encountered in registering the dimensions of the scratch after it is obtained; while Turner confesses that the standard scratch is only definitely recognised after some experience. From the standpoint of works value the Brinell, scleroscope, and Keep's drill tests are the best for manipulation; yet the sclerometer should be used for its intrinsic worth. The penetration hardness is a property not indicated or measured by any of the others.

The abrasive hardness is now measured by Saniter's test. He has shown the lack of uniformity between the wearing properties and the Brinell hardness numbers. The test follows more closely than the others, in a simple fashion, the actual stresses the material will have to withstand in practice. A good example of the need of such a test is shown in the case of Hadfield's manganese steel. With a Brinell number of about 200 it would (if judged by a standard Brinell figure) be declared soft, yet it withstands abrasion excellently and is specially suited for work where first-rate wearing properties are essential.

Another instance in which some test other than the Brinell is necessary is in the determination of the cutting efficiency of tools. Inspectors often stipulate a standard Brinell hardness and reject

number in any way. A Brinell number may be as specified and the tool fail in practice.

The Brinell test gives a measure of the tenacity; the scleroscope an approximate measure of the elastic limit; the sclerometer gives the penetration hardness; while the Saniter test indicates the wearing properties. The determination of the machining hardness, the cutting efficiency, etc., must be conducted by other means. If better terms for the different hardnesses could be adopted to prevent overlapping and confusion in the tests, there can be no doubt that greater progress in their development and more extended use would follow. I suggest that with this object the following be adopted: for Brinell hardness, the "tenacity number"; for scleroscope hardness, the "resilience number"; for sclerometer hardness, the "penetration number"; and for the Saniter test, the "abrasion number." The terms are perhaps not the best that could be devised, but something along the line suggested should be attempted.

An excellent bibliography, chronologically compiled, is given with the Report of the Research Tests Committee in the Proceedings of the Institute of Mechanical Engineers, Oct.-Dec., 1916. This Report, with the discussion and correspondence, makes a very valuable contribution to the subject of hardness testing.

My thanks are due to Messrs. Sir W. G. Armstrong, Whitworth and Co., Ltd., for permission to publish the results here given; to the Chief of the Department, Mr. O. Smalley, and to my colleague, Mr. R. N. Richardson, for their assistance in the preparation of the paper.

DISCUSSION.

Professor LOUIS expressed his indebtedness to the author for his endeavour more accurately to define the term "hardness." The engineer and metallurgist were often engaged in work which overlapped, and although each might use the same word or term, yet the meaning which each attached to that word might not be quite the same. Any attempt to clear up such discrepancies was always valuable. Many years ago, before the modern appliances for determining hardness had been brought to their present state, he had been engaged in comparing the hardness of chilled castings, in the production of which he was then engaged; he had used the simple file test, and provided that he knew the other constituents, he could fairly well predict the percentage of phosphorus. His greatest difficulty had always been with case-hardened metal. He believed that of all the modern methods, Shore's scleroscope gave the most accurate results with this class of material; in this case it certainly was better than the Brinell test, but this part of the problem was very difficult.

The whole subject of hardness was an exceedingly complex one. With regard to the term "hardness," he preferred that it should be kept to its original use, *i.e.*, as used by mineralogists. In using Turner's sclerometer, very strange results were often obtained with soft materials—as an exaggerated example, say, indiarubber. He thought that this was largely owing to the fact that before the scratch was commenced, the diamond point had first of all to penetrate into the metal. He had often wondered if it would not be better to use a rapidly revolving cylindrical test-piece and steadily to press the diamond point against the metal under well-defined pressure. In that way more accurate results might be obtained.

Mr. W. H. YOUNG said that although he was constantly using both the Brinell and Shore tests he had found them to be of comparatively little use in testing gun-metals, cast iron, and phosphor bronzes when the object of the test was to compare them as regards their use as bearing metals.

Mr. CRAGGS, in reply, pointed out that the introduction and development of many of the tests commonly used to-day, were of very recent date. Many of the old-fashioned foundry tests that had been handed down from father to son were still practiced, but a saner view was now being adopted which tended to greater uniformity in results. The difficulty to be faced now was in the correct use of the modern tests and in their interpretation. Still further information was needed. Shore's scleroscope would be the best instrument to use with case-hardened samples, since the elastic limit and the maximum stress were almost the same in such material. In very thin case-hardened samples, the soft interior would lead to erroneous results with the Brinell test, as was shown in Thomas' work, where he referred to the backing or supporting of thin samples with hard steel and with wood. He quite agreed that the term "hardness" should be limited to that used by mineralogists. The suggestion as to a revolving test-piece in conjunction with Turner's sclerometer was worth further investigation, though perhaps Keep's drill test was essentially similar to the modification of Turner's test as suggested by Professor Louis. He quite agreed with Mr. Young, but he (the author) thought he had fully indicated this by his references to Saniter's abrasion test as being the only test suitable for metals that had to withstand wear. An indication of the carbon content of ferro-chrome, where only the carbon was variable, could no doubt be obtained by the adoption of a suitable hardness test, but this would be entirely dependent upon whether a polish could be given to the sample. He agreed that wear tests produced a worked condition in the sample at the point of contact. Sir Robert Hadfield had proved this in regard to manganese steel and had given figures showing the increase in the Brinell and scleroscope readings for materials quenched in water from 950° C. and air-hardened. The suggestion put forward for the testing of tools for hardness at temperatures attained by the tool in use, had not occurred to him, but was worth following up. The futility of testing at room temperature alone must be apparent to all.

Nottingham Section.

DISCUSSION ON NITRE CAKE.

Mr. G. E. GODBER has communicated the following in connection with the discussion of November 14th last on nitre cake (see this J., 1917, 1216 A):—

In using nitre cake with common salt for the

production of hydrochloric acid and saltcake, in a mechanical furnace at about 600° C., I have to deal with three sources of supply. 1. Made on the works. Average H_2SO_4 , 32%. 2. From one of H.M. Factories. Average H_2SO_4 , 31.0%. 3. Chemical dyewares. Average H_2SO_4 , 29.5%. I have never noticed such a wide difference in the acidity as Mr. W. G. Timmans quotes in any delivery. In our own make each still residue is tested separately every day. The widest difference noted in these samples was 6%, due to extra acid having to be used to facilitate the running off process. The maximum difference in the four stills is roughly within 3%. Mr. G. C. Grisley does not say what he considers "standard quality" in saltcake. I should like to know if the following represent anything near his ideal working conditions. The average tests of 696 samples taken at regular intervals on each shift and representing together something like 1250—1300 tons, show acidity as SO_3 , 1.66%; sodium chloride, 1.81%. About 28 to 30 tons of nitre cake is used per week. I have not had much trouble in regulating the conversions providing the heat remains good. If even charging and a good temperature are maintained, the control of the conversion is greatly facilitated. The pieces of saltcake seldom come from the furnace larger than a pea. I have never had any trouble with nitrous gases.

Meeting held at Nottingham on Wednesday, February 23rd, 1916.

MR. JOHN WHITE IN THE CHAIR.

THEORY OF THE COAGULATION OF HEVEA LATEX.*

BY M. BARROWCLIFF, F.I.C.

(*late First Assistant Chemist, Department of Agriculture, Federated Malay States*).

Natural coagulation of rubber latex, unless special conditions are observed, is very slow and often incomplete, and is accompanied by putrefactive changes, causing the development of an offensive smell and discoloration of the coagulum. Whitby, in 1912, in a communication to the Congress of Applied Chemistry, mentioned that in sealed vessels which had been kept for some time coagulation had occurred without decomposition; but no significance was attached to the observation and it was not until two years later that M. Maude and W. S. Crosse, manager and engineer respectively of the Cicely Rubber Estate, discovered that this could be made the basis of a practical method for coagulating latex.†

Two theories have been advanced to account for the phenomenon by which rubber is produced by the natural coagulation of latex, without the addition of any coagulating agent. Whitby (*loc. cit.*) suggested that natural coagulation was brought about by a coagulating enzyme. This theory was based on the observation that latex can be prevented by heat from coagulating within the usual time, and that only after three or four days does coagulation, accompanied by putrefaction, again set in. He concluded that this excludes bacterial action, since natural coagulation commences within a few hours of tapping, and bacterial infection must have taken place subsequent to the latex leaving the tree.

* The substance of this paper was communicated to the Nottingham Section in February, 1916. The whole of the experimental evidence obtained is given, although publication of parts of it has been anticipated by Campbell (this J., 1917, 274), whose conclusions are in accordance with those here expressed.

† Now being worked in the F.M.S. under the name of the "M.C.T." process.

In 1915, Eaton and Grantham* advanced the view that the cause of natural coagulation is bacterial and not enzymic, and pointed out that the heating to which Whitby subjected his latex may have created conditions favourable to the development of anti-coagulating bacteria at the expense of the coagulating species.

The present writer, in 1914, carried out some experiments on the same problem and obtained results, hitherto unpublished, which supported the enzyme hypothesis, though not absolutely excluding the possibility that a bacterium capable of coagulating latex may exist also. Before describing these experiments it will be convenient first to discuss the evidence brought forward by Eaton and Grantham.

The following account is quoted from their paper:—

"Experiment 1.—Three flasks, plugged with cotton wool, containing fresh latex, were (in about 1 or 2 minutes) rapidly heated to 150° C. in a steam autoclave and slowly cooled. A slight amount of coagulation occurred, but most of the latex remained liquid. One flask, A, was opened, another, B, had a little fresh latex placed in it and was then resealed, and the remaining one, C, was left untouched. Twenty-four hours later the latex in flasks A and B was nearly completely coagulated and a yellow scum was forming on the surface. The latex in flask C was unchanged and has remained so. The flasks A and B gradually developed all the characteristic putrefactive changes. In both these cases coagulation apparently runs parallel with putrefaction.

"Experiment 2.—Three similar flasks containing latex were taken and heated in the autoclave at 90°–100° C. Two, D and E, were left untouched, and the third, F, was inoculated with a little fresh latex. On the day following partial coagulation had taken place in all three flasks. In D and E there was no trace of putrefaction. D was opened and the serum was found to be slightly acid and sweet smelling. In F a yellow scum had formed and putrefactive changes had begun. One day later E and F were completely coagulated but the putrefaction of F was more pronounced than that of E. A day later E began to develop a yellow scum and show signs of putrefaction. In both experiments there were control flasks which were not sterilised, in which the latex coagulated almost completely in the first 24 hours, formed a yellow surface scum and began to putrefy. Both the latex heated to 150° C. and 100° C. were afterwards readily coagulable with acetic acid.

"It will be seen that the results in Experiment 1 agree with Whitby's except perhaps that putrefaction was slightly more rapid. The rapidity varies greatly, however, in different experiments."

The authors attribute the coagulation occurring in D and E (Experiment 2) to a non-putrefactive bacterial change, the bacteria developing from the spores not killed by the heating to 100° C., and this received support from the fact that under conditions unfavourable to putrefactive bacterial changes coagulation could be obtained. In the presence of a small quantity of dextrose or other sugars complete coagulation occurred within 18 hours, and no putrefaction was noticed. In these instances a considerable quantity of carbon dioxide was evolved.

Several criticisms can be made against Eaton and Grantham's sterilisation experiments. In the first place the small amount of coagulum stated to have been formed during the heating may have occluded a quantity of enzyme and protected it from further action of the heat. This

enzyme would gradually diffuse out and subsequently bring about the coagulation that was in Experiment 2 actually observed.

Furthermore, it seems probable that the temperatures recorded in Experiment 1 are those of the autoclave, not of the latex.

It may seem difficult to explain, without adopting the bacterial theory, why of the two sterilised flasks the opened one coagulated whilst the untouched one did not, but in absence of more precise knowledge of the conditions of heating it may quite conceivably be supposed that in the one case enzyme was protected from destruction by the formation of a thicker clot of rubber than in the other. The following experiment, moreover, carried out by the present author, gave an entirely different result:—To 100 c.c. of rapidly boiling water was added slowly from a burette 100 c.c. of undiluted latex from old trees, the mixture being vigorously boiled throughout the addition. By this means sterilisation was effected without trace of coagulation. The resulting solution was divided into two portions and to one was added a drop of fresh latex. Both were left overnight in uncovered beakers. The following morning the solution that had been inoculated with the fresh latex had, to a large extent, coagulated, to the same degree in fact as had an unsterilised control, whilst the other portion remained perfectly liquid. It continued to have a slightly acid reaction and until the third day there were no signs of putrefactive fermentation having set in. The room in which the experiment was conducted opened out on to a rubber plantation, and there was no reason why this latex should not have become infected with the coagulating bacteria, did such exist, equally as quickly as that issuing from freshly-tapped trees. The contention that conditions suitable for anti-coagulating bacteria may have been produced cannot be sustained since the latex inoculated with fresh latex coagulated.

Whitby's conclusion that natural coagulation is attributable to an enzyme must therefore be considered valid.

Further evidence in support of the enzyme theory was then sought for. It was found that coagulation in closed vessels took place completely in normal time in the presence of toluol, the bactericide recommended by Emil Fischer as being non-toxic to enzymes. Thymol similarly did not inhibit or retard coagulation. On the other hand, hydrocyanic acid, which is fatal to nearly all enzymes, completely inhibited coagulation.

Another interesting fact ascertained was that latex sterilised in the manner described did not, contrary to that sterilised by Eaton and Grantham, behave normally when treated with the normal minimum quantity of acetic acid used in coagulating. No coagulum was formed, only, and very slowly, a flocculent, non-coherent mass. When, however, a trace of fresh latex was added, followed by the acid, a perfectly normal coagulation took place. This experiment not only supports the enzyme hypothesis, but indicates that the action of acetic acid on latex is to be considered as one of enzyme activation, and that it is not the acid *per se* which produces coagulation. This hypothesis will explain an observation made independently by Eaton and Morgan, who found that the addition to latex of a considerable quantity of strong hydrochloric acid resulted in no coagulation taking place; it may be assumed that the acid added was sufficient in quantity to destroy the enzyme.

Further support for the view that coagulation is enzymic is afforded by the fact that it was found to be greatly accelerated by the addition of very small quantities of calcium salts, a property common among enzymes. The addition of a

* Agricultural Bulletin, Fed. Malay States, Nov., 1915.

soluble calcium salt such as calcium sulphate or calcium chloride, even in as small a quantity as 0.002% of calcium, to latex contained in a closed bottle, decreased the time of complete coagulation from about 10 hours to 6 hours, whilst 0.01% of calcium reduced the time to about 4 hours.

On the other hand, when the calcium salts already present in the latex were converted into insoluble compounds, such as by the addition of neutral sodium oxalate, coagulation under similar conditions was completely inhibited.

Coagulation is also prevented, as has long been known, by making the latex alkaline; sodium citrate, however, is not an anti-coagulant. Formaldehyde, which paralyses the action of most enzymes, acts as an inhibitor also.

A further argument against the bacterial theory is that on most rubber estates there are to be found trees the latex of which coagulates almost immediately it oozes from the tree, thus stopping further flow, whereas that from neighbouring trees equally exposed to bacterial infection remains fluid as usual. In 1912, when visiting an estate on which the latex from certain blocks of trees, exposed to flooding by brackish water, exhibited to a very marked extent this property of rapid coagulation on the tree, the author tried to remedy the trouble by sponging the cuts with solutions of various antiseptics, but without effect.

It can now be suggested that this premature coagulation may be due to the presence in the latex of an abnormally large amount of soluble calcium salts, derived from the salt water. Incidentally it may be pointed out that the circumstance of this almost instantaneous tree coagulation affords evidence that the coagulating enzyme is not itself a product of bacterial action.

As already mentioned, natural coagulation only takes place completely when the latex is contained in closed vessels. The vessel must either be nearly full, or, if not, the air in the space above the latex must be under increased pressure. The explanation why coagulation is complete under these conditions and not in open vessels is most likely that in the one case the carbon dioxide which is liberated cannot escape, and so prevents the development of the putrefactive alkali-forming bacteria.

It was further found that a normal natural coagulation in closed vessels did not occur if the latex was shaken or subjected to vibration, only a small quantity of a non-coherent flocculent body resulting. In open pans the latex may be sufficiently disturbed by the gas bubbles evolved for coagulation to be adversely affected. The activity of the coagulating enzyme was found to be greatly increased by heat, and it seemed, although accurate determinations were not made, that the optimum temperature lay between 55° and 60° C. It may be deduced from this that in the Brazilian method of coagulating latex over a smoky fire, the temperature plays an important part. It would be interesting to know to what degree the coagulating enzyme is activated by the heat and by the acid fumes respectively in this process.

The strength of the evidence brought forward that the coagulation of latex is the work of an enzyme is perhaps best shown by citing for comparison the properties of the enzyme rennet and its action on milk. Rennet produces in milk, as is well known, a colloid precipitation, separating it into casein and whey. The action of rennet does not take place if the milk is even slightly alkaline. Rennet is destroyed by hydrocyanic acid and by formaldehyde, but is not affected by bactericides such as toluene. It is activated, on the other hand, by the addition of acid, also by soluble calcium salts. If, however, the calcium in the milk be converted into an insoluble oxalate

or fluoride, the action of the enzyme is altered and a series of soluble caseoses is formed instead of a coagulum of casein. The rate of action of rennet on milk increases with temperature up to an optimum of 41° C. At temperatures much above 60° C. the enzyme is destroyed. Shaking renders rennet inactive. It is thus seen that in no essential is there a difference between the enzyme coagulation of latex and of milk.

Further comparison may enable us to extend our knowledge of the former process and of its product, rubber. Milk can be coagulated by acid without rennet being present. The coagulum thus formed differs from that produced by rennet; the latter encloses all the calcium phosphates which are contained in the milk, whilst the curd produced by acid only encloses a portion, the remainder being dissolved by the acid. It will be interesting to learn whether the coagulum produced in absence of acid, with and without addition of calcium salts, contains more calcium than rubber coagulated by acid, and if so, what is the effect on the properties of the rubber.

The coagulum produced by rennet at its optimum temperature, 41° C., is very much firmer than that formed either at higher or lower temperatures. The firmness is dependent on and in inverse proportion to the percentage of water in the coagulum. Initially soft, this becomes on standing firmer and poorer in water until the maximum firmness is attained.

Precisely similar behaviour is shown by the rubber coagulum, which from being at first soft and flabby, continually hardens and contracts until, after about four days, the maximum contraction is reached, when the rubber is extremely tough and tenacious. By carrying out the coagulation at higher temperatures, up to 55° C., probably the time required for this maximum contraction would be greatly shortened.

It is interesting to note that the rate of vulcanisation decreases and the mechanical properties of the vulcanised rubber improve according to the length of time, up to four or five days, the coagulum is allowed to remain in its serum before being machined and dried.

Conclusions.

Further evidence has been brought forward that the natural coagulation of *Hevea* latex is due to the action of an enzyme, as suggested by Whitby.

It has been shown that "acid" coagulation of latex is, in all probability, also brought about by the coagulating enzyme, the acid acting as an activator of the process. Coagulation by smoke and heat according to the Brazilian method must similarly be attributed to enzyme action.

The fact that complete natural coagulation occurs in 10–12 hours in closed vessels, under certain conditions, whilst in the open it may be incomplete at the end of two or three days, is believed to be due to the prevention, by carbon dioxide, of the development of alkali by the action of putrefactive bacteria. Carbon dioxide has been stated by Eaton and Grantham to be produced by the action on sugars of bacteria normally present in latex, and some may be formed this way.

The liberation of carbon dioxide may, however, be detected even when coagulation takes place in the presence of bactericides; but there is no evidence as to whether this signifies that the gas is a product of the chemical changes that take place during coagulation or whether it is present initially and expelled through being less soluble in the separated serum than in the latex.

The author has been unable to follow up the lines of further experiment that suggest themselves owing to his departure from the East early in 1915.

Annual Meeting.

THE NATURAL ACCELERATORS OF PARA RUBBER.

BY D. F. TWISS.

(See this J., 1917, 785.)

DISCUSSION.

Mr. B. J. EATON (Kuala Lumpur, F.M.S.) writes as follows:—

I note in the paper recently communicated by Dr. Twiss at the Annual Meeting of the Society that, while crediting the writer and his collaborators with the discovery of the maturation process for obtaining a rapidly vulcanising rubber, he states that Dr. Stevens has recently traced the differences in the rate of vulcanisation of certain types of plantation Para rubber (including the "slab" rubber first so-called and discovered by the writer and his collaborators) to the decomposition of the protein matter of the retained serum during the maturing process. The writer is compelled to claim priority in respect of the latter discovery also, which is exclusively the work of the chemical laboratory of the Agricultural Department of the Federated Malay States. We have not only discovered a new type of rubber, which was first named "slab" by us, but in addition, were the first to show the nature of the changes which caused the accelerated rate of cure of such rubber and also of other types of rubber (sheet and crêpe) under certain conditions.

The significance of our second paper in this Journal (July 15, 1916) entitled "Vulcanisation experiments on plantation Para rubber (II.): The cause of variability and some contributory factors," does not appear to have been fully realised or has been overlooked by Dr. Twiss in this respect. In that paper we attributed the effects produced to the decomposition of the protein matter in slab rubber during maturation (and also in sheet, provided means were adopted to retain a certain proportion of moisture during the maturation period), and thus obviously to organic nitrogenous bases or amino acids. We also carried out the decomposition of such protein from latex (after separation from the serum by boiling) and showed definitely that the decomposed protein when added to ordinary slow-curing Para rubber (crêpe) had a very marked effect in accelerating the rate of cure.

Other experiments with decomposed casein gave similar but less marked results. At the time, the difference between the effects produced by the decomposed latex protein and decomposed casein were attributed to the probable difference in the composition of the original proteins and the consequent formation of different quantities or types of organic bases (accelerators). More recent experiments by the writer indicate that it is possible that the type of decomposition may be responsible for the difference in the effects between the two decomposed proteins, but this work is not yet complete.

In the Agricultural Bulletin, Federated Malay States (Vol. V., No. 2, November, 1916) and in various lectures before Planters' Associations in this country, during the last eighteen months, the causes have also been definitely attributed to the formation of such bases. The writer has suggested that possibly putrescine (tetramethylenediamine), which is known to be an accelerator, may be one of the bases formed.

We have, in addition, in this Journal (July 15, 1916), shown the presence of an accelerator preformed in the latex. Whether this accelerator is itself a nitrogenous base and similar to or the same substance as the accelerator formed by the

decomposition of the proteins, or a different substance entirely, remains to be proved. We have shown that the crude extract (evaporated serum, after removal of the protein coagulated by heat) is less effective, in equal quantities, than the decomposed protein material, but this may be due to different quantities of the same accelerator in the crude mixtures.

In the case of "slab" rubber, both accelerators are effective, *i.e.*, the acceleration in rate of cure of "slab" is an additive effect, since coagulum which has matured and partially dried, also retains more of the serum residue after washing and creping than coagulum which is machined on the day of or the day following coagulation.

In addition, we have shown that the decomposition changes can be followed, under certain conditions, when no other factor is involved, by the loss of nitrogen in the finished dry rubber.

In more recent experiments (this J., 1917, 1217) the writer has shown that the biological changes which take place can be accelerated by drying (incubating) slab rubber at a temperature of about 120° F.

In conclusion, Dr. Stevens' results have merely confirmed and added a little more detail to the results of the previous researches of the writer and his collaborators. The writer and his collaborators have been prevented from following up more rapidly this part of the research, by pressure of other work and further research on numerous important side issues in connection with estate practice in raw rubber preparation.

Dr. TWISS writes as follows in reply:—

In the above remarks Mr. Eaton states that the significance of the well-known investigations (this J., 1915, 989; 1916, 715) which he has made in conjunction with various collaborators, appears to have been overlooked in my recent paper (this J., 1917, 785). My statement in this connection was very brief and therefore of necessity gave an incomplete account of the matter. I agree entirely with Mr. Eaton in his view that his work led to the recognition of the probability that decomposition products of protein matter are responsible for the increased rate of vulcanisation of "matured slab" rubber, but the evidence to this effect was only circumstantial and the actual presence of organic bases of the necessary type was first directly demonstrated by Dr. Stevens in his experiments with plantation rubber (this J., 1917, 368).

Communication.

NOTES ON EXHAUST GAS ANALYSIS.

BY G. R. CLARE.

For the control of gas engines, furnaces, etc., using producer gas, it is important to know the percentage of the producer-gas used that is rejected as unburnt. This is usually ascertained by calculation from the percentages of carbon dioxide, carbon monoxide, oxygen, and hydrogen found by the ordinary gas-analytical methods. The amount of methane present in the producer gas being so small (1 to 4%) it is considered unnecessary to estimate it separately in the exhaust.

This method being rather tedious owing to the slow absorption of oxygen by pyrogallol and the time spent on calculation, and in view of the fact that an approximation only is needed, the writer found on investigation that the time spent on both the analysis and the calculation could be shortened to at least one quarter. Only the carbon dioxide and monoxide and hydrogen are

estimated, the estimation of oxygen being eliminated and the calculation reduced to a simple formula (and curve if necessary) which are arrived at as follows:—

The percentage of burnt producer gas present in the exhaust is given by:—

$$100 \times \frac{(\% \text{ of perfect exhaust gas in the exhaust gases})}{\text{Perfect exhaust gas per 100 vols. of producer gas.}} \quad (\text{i.})$$

The perfect exhaust is the volume which would be formed by the complete combustion of 100 volumes of producer gas with just the requisite amount of air, and consists solely of carbon dioxide and nitrogen, the water vapour formed being condensed. The volume of CO_2 formed is the sum of the % of CO_2 , CO , and CH_4 present in the producer gas, while the volume of nitrogen is the sum of the nitrogen present in the producer gas and the nitrogen necessarily introduced in the air with the consumed oxygen. The CO_2 due to perfect exhaust gas present is obtained by subtracting the CO_2 due to the unburnt gas from the CO_2 in the mixed exhaust gases.

$$\text{Therefore the \% perfect exhaust present is:—} \\ 100 \times \frac{(\% \text{CO}_2 \text{ in exhaust gases—CO}_2 \text{ due to unburnt gas present})}{\text{CO}_2 \text{ in 100 volumes of perfect exhaust.}} \quad (\text{ii.})$$

The CO_2 in 100 volumes perfect exhaust we have seen is:—

$$\frac{100 \times (\% \text{CO}_2 + \% \text{CO} + \% \text{CH}_4 \text{ in producer gas})}{\text{Volume of perfect exhaust formed by 100 volumes producer gas.}} \\ \text{Substituting we have:—}$$

$$\frac{(\% \text{CO}_2 \text{ in exhaust gases—CO}_2 \text{ due to unburnt gas}) \times \text{volume of perfect exhaust per 100 vols. producer gas}}{\% \text{CO}_2 + \% \text{CO} + \% \text{CH}_4 \text{ in producer gas.}} \quad (\text{iii.})$$

The burnt gas is therefore given by this formula

$$\frac{100}{\text{Volumes perfect exhaust per 100 vols. producer gas}} \\ \text{which works out to}$$

$$100 \times \frac{(\% \text{CO}_2 \text{ in exhaust—}\% \text{CO}_2 \text{ due to unburnt gas})}{\% \text{CO}_2 + \% \text{CO} + \% \text{CH}_4 \text{ in producer gas}} \quad (\text{iv.})$$

We will now assume that the producer gas has the following mean composition:—16% CO_2 , 11% CO , 26% H_2 , 3% CH_4 , 44% N_2 and no oxygen. These particular figures are taken as an example, as they work out to a simple formula.

Then $\frac{16}{40} \times \% \text{combustibles in the exhaust}$ may be substituted for the $\% \text{CO}_2$ due to unburnt gas present in the exhaust, and

(iv.) becomes:—

$$\frac{\% \text{CO}_2 \text{ in exhaust—} 0.4 \times \% \text{combustibles in exhaust}}{0.3} \quad (\text{v.})$$

The percentage of unburnt gas in the exhaust being $\frac{100}{40} \times \% \text{combustibles present}$, the percentage of producer gas used which is rejected as unburnt gas is:—

$$\frac{75 \times \% \text{combustibles in exhaust}}{\% \text{CO}_2 \text{ in exhaust} + 0.35 \times \% \text{combustibles in exhaust}} \quad (\text{vi.})$$

It is obvious now that at any fixed percentage of gas unburnt the value

$$\frac{\% \text{Combustibles in exhaust}}{\% \text{CO}_2 \text{ in exhaust}}$$

must be fixed also.

Substituting values and plotting them a regular curve is obtained.

% Combustibles % CO ₂	0.068	0.140	0.215	0.294	0.377	0.465	0.558	0.656
% Gas unburnt	5	10	15	20	25	30	35	40

Given an analysis of exhaust gas in terms of $\% \text{CO}_2$, CO , and H_2 , we see at a glance the percentage of the gas used which is rejected as unburnt. It will be found that this formula and curve are sufficiently accurate for practical purposes even when the composition of the producer gas varies fairly considerably.

By this method an analysis may be completed and the required value obtained in five minutes' time, which is a great saving over the old method.

Of course, other values may be substituted for the sample analysis of producer gas taken and a slightly modified formula and curve obtained; as previously mentioned, that particular set of figures was used to give a simple formula.

Canadian Section.

Meeting held at Toronto on Friday, December 21st, 1917.

MR. S. B. CHADSEY IN THE CHAIR.

HISTORY OF THE NICKEL INDUSTRY SINCE 1910.

BY E. P. MATHEWSON, B.Sc. (MICHIG.).

(Abstract.)

The history of the nickel industry in Canada and the United States was the subject of a most interesting address by the late D. H. Browne, before this section of the Society in January, 1911 (see this J., 1911, 248). This paper is intended to fill in the gap between that date and the present in the history of the nickel industry.

In the first place, the use of nickel has increased immensely during the past seven years, and the great war has emphasised its importance to a very large extent. Some of the greatest engineering structures of the world have been recently completed, and but for the use of nickel as an alloy in the steel employed, their construction would have been entirely out of the question. One of the most recent of these structures is the new Quebec Bridge.

The lack of nickel in Germany after the first few months of the war caused our enemies to offer great inducements to producers to supply them with nickel. They were successful in securing a supply from Norway, which, however, by means of certain negotiations on the part of the British Government, was cut off almost entirely, and in May of 1917, the refinery at Kristiansands was damaged by fire to such an extent that no nickel has been produced at that plant since that time.

The affair of the Deutschland is familiar to all and caused a feeling of uneasiness amongst the Allies at the time.

It is no secret to state that the nickel producers, particularly the International Nickel Company, of which the Canadian Copper Company is the chief subsidiary, became much alarmed at what they considered a lack of market for nickel proportionate to their producing capacities.

Just before the war broke out, the manufacturers of structural steel seemed suddenly to become aware of the value of nickel steel and its use was increasing rapidly. When the war broke out, the demand for nickel in the war industries absorbed the entire supply, and it is generally believed that after the war the demand for nickel will continue to a still greater extent.

In connection with the automobile industry, the consumption of nickel is quite large and growing constantly. For making of shafting, particularly marine shafting, nickel seems to be essential, but the great consumption of the metal will be in the form of nickel steel alloy for structural purposes.

Within the past few years, the enormous reserves in the lower levels of the Creighton Mine have been discovered, and at present a very important investigation is being made by the Mond Nickel Company on the lot west of the Creighton Mine, where diamond drilling is being undertaken with the object of striking the Creighton ore body extension at a depth of 3800 feet. This is twice the depth of any of the workings in the nickel region of Canada. Some very interesting diamond drilling has been undertaken in the Eastern part of the Sudbury district by the Long-

year Company, they having drilled through 100 feet of wash and found nickel ores at some distance below the wash.

Among interesting changes in smelting are the following: The Mond Nickel Company has moved to a point eight miles east of Sudbury on the Canadian Pacific Railway and constructed a modern smelter and model town called Coniston.

The old Murray Mine is now the principal holding of the British America Nickel Corporation, Ltd., which is the successor of several of the older companies. The depression in financial circles at the beginning of the war had its effect on the nickel industry and particularly on this company, and work was suspended. But later, as the company owned the Hybinette patents for refining nickel, which are considered very valuable and which had been in operation for a number of years at the Kristiansands refinery, Norway, it was decided to resume the construction of the plant at Nickelton, and this work is now well under way.

Some time ago nickel became a political issue in Canada, but with the entry of the United States into the war on the side of the Allies, this ceased to interest politicians. However, one good result of the nickel agitation was the appointment of the Royal Ontario Nickel Commission, which recently completed its labours and published a voluminous report which is generally considered to be the finest thing of the kind ever offered to the public (see this J., 1917, 499).

Since the report of the Commission has been made public, the rate of taxation on nickel properties has been materially increased, with a corresponding increase in revenue to the Government, which more than justified the expense of the Commission.

The importance of Canada as a nickel producer has been maintained through all these years, and it now is apparent that the country will soon become equally important in the refining of nickel.

The International Nickel Company has under construction, and near completion, a modern refinery at Port Colborne, Ontario, which will have an initial capacity of 7500 tons of nickel per annum, and provision has been made for enlargement to double that capacity.

The British America Nickel Corporation's plant will be nearly the same size as the Port Colborne plant, but will utilise the Hybinette electrolytic process, which is quite distinct from that used by the International Nickel Company, and in it also will be made provision for enlargement as the needs of the industry demand. This plant, however, will not be completed until the year 1919.

MR. A. T. SMITH IN THE CHAIR.

VITAMINES.

BY PROF. W. RAMSDEN.

(Abstract.)

It has been discovered during the last 20 years that animals as various as pigeons, fowls, rats, pigs, and man if fed exclusively on polished rice develop the disease known as beri-beri, characterised by serious changes in the peripheral nerves, and that a water, or 90% alcohol, extract of the

rice-polishings contains a substance of which very minute quantities prevent or cure the disease.

By careful and laborious experiments with rice and other diets it has been shown that this substance is widely spread in the common foodstuffs and that its presence is essential for life. Attempts to isolate it in a pure state in sufficient quantity for chemical investigation have not hitherto been completely successful, but enough has been ascertained to make certain that it is neither a protein, fat, nor carbohydrate, nor indeed any of the known constituents of plants or animals. It is free from phosphorus, insoluble in absolute alcohol, ether, benzene, acetone, or oils, soluble in water or 90% alcohol, and is adsorbed by fullers' earth or animal charcoal. It survives a good deal of cooking at 100° C. but is slowly destroyed at 120°. It is resistant to 5% sulphuric acid. Funk has proposed for it the name "the anti-beri-beri vitamine" and this term "vitamine," although open to many objections, has been widely adopted for substances of this type. The name "sitaoid," meaning a medicine-like substance associated with food, is suggested by the writer as accurately descriptive and not implying a knowledge of their chemical characters which we do not possess.

Most foodstuffs contain adequate amounts of the anti-beri-beri substance but, it is important to note, white flour, polished rice, and arrowroot, and probably also "corn-flour," and much of what is sold as sago, tapioca, and semolina, contain none. Ordinary white bread doubtless contains a little derived from its yeast, but certainly not enough for health unless supplemented by other foodstuffs. Wheat-bran contains a little, wheat-embryo contains a good deal.

It has also been discovered, thanks mainly to the pioneer researches of Hopkins, Stepp, Osborne and Mendel, and McCollum and his collaborators, that rats and mice require not only the anti-beri-beri substance in their diet but at least one other vitamine or sitaoid, and in its absence get sore eyes (Xerophthalmia) and are unable to grow. It will be convenient to refer to this as the anti-sore eyes substance (McCollum's Fat-soluble A).

As found in animal substances it is slightly soluble in water but much more so in oils, ether, and hot alcohol. It is very resistant to ordinary cooking operations, but is slowly destroyed by prolonged exposure to daylight. It has not been identified with any of the chemically known constituents of plants or animals. It is either completely free from phosphorus and nitrogen or, alternatively, it is active in incredibly minute amounts. As found in the higher plants it is insoluble in ether, oil, or hot alcohol. The relations between the plant and the animal anti-sore eyes substances have not yet been ascertained. Proved to be indispensable for mice and rats, and especially for the growth of the young, there are strong reasons also for suspecting it to be equally indispensable for man. It is present in quantity in yolk of egg, cod liver oil, all animal fats investigated (with the remarkable exception of lard), milk, cheese, butter, margarine made from animal fats, green leaves, soya beans, millet, and flax seed. It is absent from lard and all vegetable oils (almond, maize, cottonseed, sunflower seed, linseed, and soya bean oils) and margarines made from them. It is present, although apparently in small amount only, in the (entire) seed of wheat, oats, maize, hemp, rye, and cotton seed.

There are strong reasons for believing that lack of yet a third vitamine or sitaoid is mainly responsible for the disease known as scurvy. This anti-scorbutic substance is remarkable in that although surviving ordinary cooking operations it usually fails to survive slow drying or long "preservation" of the food in which it is contained. It is present in all fresh vegetables, fruit, or meat.

It is rarely or never present in dried vegetables. It is absent or inadequate in amount in dried seeds, but it is present in seeds, e.g., barley, peas, which have just been allowed to germinate (Furst, Weill and Mouriquand, Miss Chick).

McCollum's observation that guinea-pigs on a diet of oats do not get scurvy if given laxatives is explicable on the assumption that the anti-scorbutic substance is essential for the normal functioning of the intestine.

The table given below indicates some of the commoner foods in which one or more of the three vitamins have been definitely proved present or absent. The feeding experiments necessary for each such proof are time-consuming and demand very many precautions. Anything like exact comparisons is at present impossible, and the number of plus signs in the table indicates merely the general impression conveyed by the different observers.

* Milk vitamine-content depends largely on the mother's diet.

There is evidence that unless a nursing mother is obtaining adequate amounts of the first two vitamins in her food the milk she produces is deficient in these bodies. Adults tolerate lack of these substances in food much longer than young growing animals.

It is clear that the facts of which a brief account has been given above are of much importance to this community, and should be widely known.

DISCUSSION.

Mr. A. T. SMITH said that bread made from white flour was an example of human interference with nature's providence, since the outer portions of the wheat-berry (which, if included, would give a darker flour) contained much more of the vitamins than the central portion of the grain.

Prof. MACDONALD mentioned that the medical profession in Liverpool had done much work in connection with beri-beri and similar diseases, and he thought the subject of Prof. Ramsden's discourse was very important.

Dr. A. HOLT asked what would be the effect of giving an animal a diet abnormally rich in anti-beri-beri substance.

Mr. J. TWOMEY wished to know if there were any theories of the action of vitamins in the body.

Prof. RAMSDEN, in reply, said that presumably large amounts of vitamins had no further effect, i.e., a certain quantity of the substance was required by the animal and above this any excess was metabolised or eliminated. Anti-beri-beri substance would not long survive a temperature of 130° C. To formulate any theory of the action of vitamins would be too speculative until more was found out about their chemical

constitution, etc. The anti-scorbutic vitamin seemed to be preserved in the juice or extract of limes, oranges, and lemons. Green vegetables contained large amounts of all three vitamins. Dr. Mori of Japan had found 400 cases of conjunctivitis in children due to a diet of cereal food lacking in fat-soluble A vitamin. Dry peas and beans contained little or no anti-scorbutic vitamin, but if they were allowed to germinate for 18 hours they became rich in this body.

MR. WILLIAM THOMSON IN THE CHAIR.

THE OXIDATION OF RUBBER.

BY S. J. PEACHEY AND M. LEON.

In a paper read before the Manchester Section of this Society in 1912, one of the authors described a simple form of apparatus designed for the purpose of carrying out quantitative investigations on the oxidation of rubber by air (this J., 1912, 31, 1103). As the result of a series of experiments on carefully purified rubber it was shown:—(1) that the reaction between rubber and oxygen, which under ordinary conditions is so slow as to be imperceptible, becomes sufficiently rapid at a temperature of about 85° C. to render possible direct observation of the volume of gas absorbed; (2) that the presence of a normal amount of natural resin (about 3% for the type of rubber employed) exerts a marked retarding effect on the rate of oxidation; (3) that the amount of oxygen ultimately taken up by the unit molecule of rubber ($C_{10}H_{16}$) corresponds closely to four atomic proportions.

The work has now been extended in several directions with the results recorded below.

Action of dry oxygen on purified plantation rubber.

In the experiments referred to above a weighed quantity of purified raw rubber (*i.e.*, rubber freed from resins and proteins) was deposited in the form of a thin film on the interior surface of a flask connected with a measuring burette containing mercury, the whole apparatus (*loc. cit.* Fig. 1) being filled with a known volume of moist oxygen. The flask was heated in a water bath at a constant temperature of 85° C. and the volume of oxygen absorbed was periodically measured as long as absorption took place. The rate of oxidation of the rubber was thus observed and the total amount of oxygen taken up was readily determined. Under such conditions it was found, as previously stated, that for every unit molecule ($C_{10}H_{16}$) of rubber oxidised, the amount of oxygen absorbed approximated very closely to four atomic proportions. In these experiments the assumption was made that the residual gas consisted wholly of oxygen and that no volatile products, or at least none possessing an appreciable vapour pressure, were produced during the oxidation. That this assumption is not quite justified is shown later.

In order to ascertain whether either the speed

of the reaction or the amount of oxygen ultimately taken up was influenced by the presence of moisture, it was considered desirable to carry out parallel experiments using carefully dried oxygen. For this purpose the apparatus previously described was employed, but the oxygen, instead of being saturated with water vapour as in the earlier experiments, was carefully dried by passing through tubes containing solid potassium hydroxide and phosphorus pentoxide respectively. The film of rubber also was dried *in vacuo* over phosphorus pentoxide. It was found that in these circumstances the rubber underwent oxidation at practically the same rate as when moist oxygen was employed and that the amount of gas taken up was very nearly the same in the two cases. This is illustrated by curve B (Fig. 1), which represents the oxidation of purified rubber by dry oxygen; curve A represents the result of a parallel experiment with moist oxygen and is included for comparison. In a typical experiment 0.2413 gm. of rubber absorbed 78.9 c.c. of oxygen (dry) measured at 0° C. and 760 mm. pressure, a volume which corresponds to an absorption of 3.97 atoms of oxygen per unit molecule ($C_{10}H_{16}$) of rubber. It appears therefore that the presence or absence of moisture exerts no appreciable influence on the course of the reaction.

Formation of carbon dioxide during the oxidation of rubber.

In the earlier experiments on the behaviour of rubber towards moist oxygen at a temperature of 85° C., it was assumed that the gas remaining in the absorption apparatus after the reaction consisted of oxygen only and that the oxidation of the rubber was not accompanied by the formation of an appreciable quantity of any product possessing a measurable vapour pressure at the ordinary temperature (except water, which was present throughout). A more careful examination of the residual gas has now revealed the presence of an appreciable and somewhat variable amount of carbon dioxide, which appears to be a normal product of the oxidation. Portions of the residual gas were drawn off with the aid of a Sprengel pump and analysed in a Haldane apparatus. The results obtained in a number of experiments are shown in columns 3 and 7 of the accompanying table. It will be seen that during the oxidation of a molecule ($C_{10}H_{16}$) of rubber approximately one quarter of an atomic proportion of carbon is converted into carbon dioxide. At first sight this might suggest that the rubber complex must contain at least 40 atoms of carbon, but it is more probable that the formation of carbon dioxide is the result of a secondary reaction.

The conclusion previously arrived at, *viz.*, that approximately four atoms of oxygen are absorbed during the oxidation of the $C_{10}H_{16}$ unit of the rubber molecule, is confirmed by the later experiments and is not in any way affected by the observation that a certain amount of carbon dioxide is produced during the reaction and is included in the measurement of the residual oxygen. The carbon dioxide is formed, however, from an equal volume of oxygen and it follows that the amount of oxygen interacting with the rubber is somewhat greater than that which is absorbed and which is contained in the resinous oxidation product. The figures given in columns 5 and 6 represent respectively the number of atoms of oxygen taken up by the unit molecule of rubber to form resinous oxidation products, and the total number of atoms of oxygen interacting with the rubber. The latter are not very concordant and do not approach very closely to whole numbers, and it is not easy in the present state of our knowledge to interpret their significance.

TABLE I.

* Dry oxygen was used in this experiment.

Action of moist oxygen on vulcanised rubber.

The results of the experiments described in this and in the earlier communication are of considerable interest from the purely chemical standpoint, but in that raw rubber finds very few applications in the industries it is naturally of greater importance from the point of view of the technologist that some knowledge should be gained regarding the behaviour of vulcanised rubber on prolonged exposure to air or oxygen. The results of some preliminary experiments in this direction are here recorded.

The apparatus employed was that previously described. In order to obtain a thin film of vulcanised rubber suitable quantities of a solution of raw rubber in benzene and a standard solution of sulphur in the same solvent were run into the flask, which was then rotated slowly while the solvent was evaporated in a current of air. The film was subsequently dried *in vacuo* until constant in weight. The flask was then heated in an oil bath, provided with an agitator, to a temperature of $140^{\circ}C$. for $2\frac{1}{2}$ hours. The rubber employed was pale plantation crêpe and experiments were made with both the acetone-extracted rubber and with that containing a normal percentage (3.08) of natural resin. 0.2528 gm. of acetone-extracted rubber was vulcanised as described above with the addition of 0.0256 gm. of sulphur, corresponding to 9.2% on the weight of the mixture. The volume of oxygen absorbed amounted to 92.3 c.c. measured at $0^{\circ}C$. and 760 mm. pressure, corresponding to 4.43 atoms of oxygen per unit molecule of rubber.

0.2497 gm. of raw rubber containing 3.08% of natural resin was vulcanised with the addition of 0.0217 gm. of sulphur, corresponding to very nearly 8%. The volume of oxygen absorbed amounted to 77.9 c.c. measured at $0^{\circ}C$. and 760 mm. pressure, equivalent to 3.79 atoms per unit molecule of rubber. The residual gas was found to contain 0.0137 gm. of carbon dioxide—an amount which would be produced by the oxidation of 0.16 atom of carbon per molecule of rubber. No sulphur dioxide was formed.

The relative rates of oxidation of the resin-free and resin-containing samples of vulcanised rubber are illustrated in Fig. 1, the curves (C and D) being obtained by plotting the volume of oxygen absorbed against the time of heating. It will be seen that, as in the case of unvulcanised rubber, the presence of the natural resin greatly retards the rate of oxidation. Whilst the oxidation of the resin-free sample was complete in 314 hours, that of the resinous rubber required a period of nearly 800 hours.

Further, it will be seen that vulcanised rubber, whether resinous or resin-free, oxidises far less rapidly than the corresponding raw rubber, although the amounts of oxygen ultimately taken up are of the same order in the two cases. This latter observation, taken in conjunction with the fact that sulphur dioxide does not appear amongst the products of the reaction, suggests that during

the oxidation of vulcanised rubbers neither the free nor the combined sulphur suffers attack.

The product of the oxidation of vulcanised rubber remains adhering to the flask in the form of a highly lustrous, dark brown and brittle film which could not be brought into solution by treatment with any organic solvent and which resisted the action of alkalis and moderately strong mineral acids. An examination of this product and of that formed by the oxidation of raw rubber is in progress.

Oxidation of balata.

In order to ascertain whether the mode of oxidation of balata differed in any essential point

FIG. 1.

from that of rubber, a quantity of the highly purified material was prepared and its oxidation studied by a similar method to that described above.

Good block balata was shredded and after thorough extraction with acetone was dissolved in warm light petroleum, the solution being then filtered and precipitated with alcohol. The precipitated balata was well washed with fresh alcohol, again dissolved in light petroleum, and precipitated with acetone; after washing with acetone it was once again dissolved in light petroleum and the solution cooled with ice. The balata separated as a pure white coagulum which was washed with a little ice-cold petroleum and dried *in vacuo*. The dried material was dissolved in pure benzene and the resulting solution was employed for producing thin films on the interior

surface of the oxidation flask. The oxidation was carried out with moist oxygen at a uniform temperature of 85° C.

The figures obtained are shown in Table II. They are quite concordant in the two experiments and appear to indicate that the oxidation of balata differs from that of rubber in that five atoms of oxygen are absorbed during the oxidation of a molecule of the hydrocarbon; in other words the resinous products of the oxidation of balata collectively contain an atom of oxygen more than those formed from rubber. Further, the amount of carbon dioxide produced corresponds with the oxidation of one-third of an atomic proportion of carbon per unit molecule of balata entering into reaction, as against one-fourth of an atomic proportion in the case of rubber. It is evident, therefore, that the mechanism of the oxidation differs in the two cases and it is to be presumed consequently that the two hydrocarbons differ essentially in constitution. It is anticipated that an investigation into the nature of the oxidation products may throw further light on this subject; such an enquiry is, however, beset with difficulties, mainly on account of the colloidal nature of the substances formed, which renders their separation and characterisation extremely tedious.

The rate of oxidation of the purified balata is comparable with that of raw rubber freed from resin, and by plotting the volume of oxygen absorbed against the time of heating, a curve (Fig. 2) is obtained, the first half of which, representing the early stages of the oxidation, is very similar to that shown in Fig. 1 (A). In each

FIG. 2.

case the oxidation commences after a few hours' heating and proceeds very rapidly during a period of from twenty to thirty hours, but beyond this point the curves diverge widely. Whilst the oxidation of the rubber is completed rather abruptly in a period of well under 100 hours, that of the balata suffers a gradual deceleration and requires for completion a period three times as long.

Products of the oxidation of rubber.

The investigation of the products of the oxidation of rubber presents numerous difficulties. Rubber is essentially a colloidal substance and up to the present every compound directly derived from it has proved to possess a similar physical character. The isolation and characterisation of such compounds constitutes an exceedingly laborious task in that the ordinary processes of separation and the usual criteria of purity are in almost every case inapplicable. Fractional precipitation from different solvents is the only available method of purification, and ultimate analysis at each stage of this process is the only means for ascertaining whether a product presents the character of a pure substance. Having arrived at a constant composition it is still impossible to state with certainty that the product in question is an individual substance.

In spite of these difficulties, however, a certain amount of progress has been made, and in view of the fact that the work has been unavoidably interrupted for the present, the authors feel that it is desirable to record the results so far obtained, although any conclusions drawn from them may need revision at a later date.

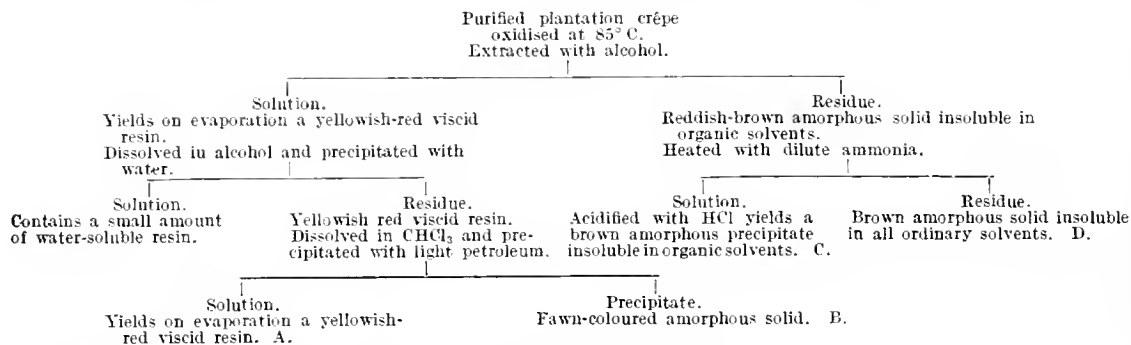

In the earlier paper on the oxidation of rubber (*loc. cit.*) it was shown that when a thin film of rubber averaging from 0.2 to 0.4 gm. in weight is exposed to the action of oxygen at a temperature of 85° C. until absorption of the gas ceases, the product of the reaction dissolves almost completely in alcohol, and on evaporation of the solvent is obtained in the form of a yellowish-red and highly viscid gum. The quantities obtained in this manner are too small to permit of a thorough investigation.

In order to obtain sufficient material for examination, about 50 grms. of extracted plantation rubber was oxidised continuously over a period of six months by exposing in shallow dishes to an atmosphere of oxygen in an electrically heated oven maintained at a temperature of 85° C. The oxidising rubber was periodically extracted with alcohol at intervals of 48 hours, the soluble products being thus removed and fresh surfaces of rubber exposed. The result of this treatment was found to differ unexpectedly from that of the small scale experiments in that exhaustive oxidation of the masses of rubber yielded, in addition to the alcohol-soluble gum, an insoluble and highly stable residual product incapable of undergoing further change under the conditions of the experiment. In its resistance to chemical attack this substance appears to be comparable with cellulose. The alcoholic extract was evaporated to a convenient bulk and mixed with a large excess of water, whereby the bulk of the dissolved gummy products was precipitated, the aqueous liquor yielding on evaporation a small quantity of a product soluble in water. The precipitated material was dried at 80° C., dissolved in chloroform, and by the addition of petroleum ether was separated in the form of a sticky mass, which, by repeated solution and fractional precipitation, was ultimately obtained in the solid form. The chloroform-petroleum liquors yielded on evaporation a yellowish-red viscid resin.

TABLE II.

	Balata.	Oxygen absorbed.	Carbon dioxide produced.	Oxygen interacting.	No. atoms oxygen taken up by $C_{10}H_{16}$.	No. atoms oxygen interacting with $C_{10}H_{16}$.	Atomic proportion of carbon oxidised to CO_2 per $C_{10}H_{16}$.
I. ..	gm., 0.2274	gm., 0.1372	gm., 0.0259	gm., 0.1558	5.13	5.82	0.35
II. ..	0.3034	0.1859	0.0360	0.2118	5.21	5.93	0.36

A tedious recital of the numerous devices of fractionation employed is unnecessary here, and it will suffice to indicate diagrammatically the scheme employed in separating what appear to be individual substances from a somewhat complex mixture of oxidation products.

It will be seen that four main products were obtained. The alcohol-soluble portion of the oxidised rubber yielded the two substances, A and B, the one being soluble, the other insoluble in light petroleum. The alcohol-insoluble residue was resolved into the two substances, C and D, the one soluble in aqueous alkalis, the other insoluble. None of the four substances contained nitrogen, although this was found to be present in the small amount of water-soluble product previously mentioned, a fact which suggests that the latter is derived from the protein of the rubber. Substances A and B were purified by solution and precipitation processes until they attained a constant composition; the final analytical results were as follows:—

Substance A.

- (1) 0.2078 grm. gave 0.5491 grm. CO_2 and 0.1872 grm. H_2O .
- (2) 0.2259 grm. gave 0.5973 grm. CO_2 and 0.2039 grm. H_2O .

whence $\text{C} = 72.07, 72.11$; $\text{H} = 10.01, 10.03\%$. These figures agree closely with the formula $\text{C}_{16}\text{H}_{26}\text{O}_3$, which requires $\text{C} = 72.18$ and $\text{H} = 9.81\%$.

Substance B.

- (1) 0.0902 grm. gave 0.2102 grm. CO_2 and 0.0645 grm. H_2O .
- (2) 0.0796 grm. gave 0.1859 grm. CO_2 and 0.0560 grm. H_2O .

A second specimen of B prepared by oxidising a film of rubber in a flask gave similar figures:—

- (3) 0.2043 grm. gave 0.4723 grm. CO_2 and 0.1471 grm. H_2O .
- (4) 0.3050 grm. gave 0.7096 grm. CO_2 and 0.2212 grm. H_2O .

whence $\text{C} = 63.41, 63.69, 63.05, 63.45$; $\text{H} = 7.91, 7.82, 8.00, 8.06\%$. These figures agree fairly closely with the formula $\text{C}_6\text{H}_9\text{O}_2$, which requires $\text{C} = 63.71$ and $\text{H} = 7.97\%$.

Substances C and D.

The insoluble mass left after exhausting the oxidised rubber with alcohol was finely ground and extracted in a Soxhlet apparatus with acetone, benzene, and chloroform successively. It was found to be partly dissolved by prolonged boiling with dilute ammonia solution, and this treatment was carried out exhaustively, the ammonia extracts being subsequently precipitated by the addition of hydrochloric acid.

The original insoluble residue, which constituted about 50% of the total oxidation products, was thus separated into approximately 20% of a brown

amorphous and brittle solid, soluble in alkalis (substance C) and 80% of a reddish coloured amorphous substance, insoluble in alkalis and in all the common organic solvents (substance D). After repeated extraction with boiling water these products were dried and analysed.

Substance C.

- (1) 0.1432 grm. gave 0.3293 grm. CO_2 and 0.0982 grm. H_2O .
 - (2) 0.1402 grm. gave 0.3230 grm. CO_2 and 0.0938 grm. H_2O .
- whence $\text{C} = 62.71, 62.83$; $\text{H} = 7.62, 7.43\%$. $\text{C}_{11}\text{H}_{16}\text{O}_4$ requires $\text{C} = 62.46$; $\text{H} = 7.55\%$.

Substance D.

- (1) 0.1199 grm. gave 0.2778 grm. CO_2 and 0.0895 grm. H_2O .
 - (2) 0.0954 grm. gave 0.2227 grm. CO_2 and 0.0688 grm. H_2O .
- whence $\text{C} = 63.19, 63.67$; $\text{H} = 8.29, 8.01\%$. $\text{C}_6\text{H}_9\text{O}_2$ requires $\text{C} = 63.71$ and $\text{H} = 7.97\%$.

The following is a brief summary of the properties of these products in so far as these have been determined.

Substance A, possessing a composition agreeing with the formula $\text{C}_{16}\text{H}_{26}\text{O}_3$, is a clear, brownish-yellow resin of neutral character. It is insoluble in water but possesses a remarkably wide range of solubility in organic solvents; it is freely soluble for example in alcohol, acetone, ether, ethyl acetate, amyl alcohol, amyl acetate, acetic acid, formic acid, glycerol, chloroform, carbon tetrachloride, carbon bisulphide, light or heavy petroleum, phenol, benzene, naphthalene, aniline, and pyridine.

Attempts to obtain derivatives of the substance by treatment with the usual reagents have mostly failed so far; nitric acid, however, attacks and dissolves the substance, and the addition of water precipitates a yellow compound which has not yet been obtained in a pure condition.

Substance B, which in composition agrees with the formula $\text{C}_6\text{H}_9\text{O}_2$, is a fawn-coloured amorphous powder of feebly acidic character. It possesses no very definite melting point but softens and begins to intumesce at 132°C , gradually swelling as the temperature is raised until it occupies three times its original volume; it does not char below 250°C . On heating 0.3 grm. of the substance in a small tube connected with a bulb containing barium hydroxide, no evolution of carbon dioxide could be detected.

The substance is insoluble in water, ether, light petroleum, and carbon bisulphide; it dissolves freely in alcohol, acetone, ethyl acetate, amyl alcohol, amyl acetate, chloroform, phenol, naphthalene, and pyridine, and with difficulty in benzene. Dilute acids are without action, but concentrated hydrochloric acid dissolves the substance yielding a dark brown solution; on warming a vigorous reaction sets in, accompanied by considerable charring. Concentrated nitric acid dissolves the

substance in the cold, yielding a reddish-brown solution which evolves nitrous fumes copiously on warming and on dilution with water throws down a flocculent yellow precipitate. After drying this substance darkens somewhat at 185°C , but does not melt or char below 250°C . Substance B dissolves readily in dilute caustic soda and the solution when shaken with benzoyl chloride yields a brown mass which after washing and drying forms a granular powder bearing a close resemblance to D. It is insoluble in all the common organic solvents.

Attempts to determine the molecular weight of B by the ebullioscopic method resulted in failure, no elevation in boiling point being observable in a 1–2% solution in chloroform or benzene. Titration of the substance with $N/20$ solution of caustic soda yielded figures of doubtful value owing to the indefiniteness of the end point.

The neutralised solution yielded precipitates with most metallic salts, but on examination these proved to consist of the original colloidal material.

Oxidation by potassium permanganate in dilute alkaline solution appears to yield oxalic acid as the main product, identified by the analysis of its barium salt. The addition of powdered permanganate to an acetone solution of the substance yields a brown gummy product readily soluble in water, alcohol, acetone, and chloroform, but insoluble in light petroleum. This substance was purified by repeatedly dissolving in chloroform and precipitating with petroleum spirit, and was finally obtained in the form of a light yellow powder which remains unchanged on heating to a temperature of 250°C .

Substance C agrees in composition with the formula $\text{C}_{11}\text{H}_{16}\text{O}_4$. This product, which appears to possess an acidic character, has been superficially examined only.

Substance D appears to have the same composition as B, but is widely different in properties. It forms a gritty powder of a reddish-brown colour and a faint odour recalling that of naturally occurring rubber resin. Heated above 250°C , it chars without melting, emitting an odour resembling that of a burning carbohydrate.

Its resistance to the action of solvents is quite remarkable; it is insoluble in water, aqueous alkalis, alcohol, acetone, ether, ethyl acetate, amyl alcohol, amyl acetate, acetic acid, chloroform, carbon tetrachloride, carbon bisulphide, glycerin, petroleum spirit, benzene, phenol, aniline, pyridine, and piperidine. Formic acid appears, however, to attack the substance on prolonged boiling, partly dissolving it to form a brownish-coloured solution from which a yellow granular substance is precipitated on the addition of water; this, on drying, forms a fine yellow powder readily soluble in chloroform but insoluble in light petroleum. In appearance and in solubility it closely resembles B. A quantity of the material was purified by precipitation from chloroform solution, and on analysis yielded the following figures:—

0.1078 grm. gave 0.2533 grm. CO_2 and 0.0708 grm. H_2O .

0.0872 grm. gave 0.2045 grm. CO_2 and 0.0559 grm. H_2O , whence $\text{C}=63.90$, 63.96% ; $\text{H}=7.29$, 7.12% . $\text{C}_9\text{H}_{14}\text{O}_2$ requires $\text{C}=63.71$ and $\text{H}=7.97\%$.

The residue from the formic acid treatment resembled the original substance D, being insoluble in all the ordinary organic solvents; in colour, however, it was almost black. Its composition was not definitely established.

Substance D is not attacked by dilute mineral acids, but concentrated hydrochloric and sulphuric acids produce a considerable amount of charring.

Concentrated nitric acid attacks the substance vigorously, forming a brownish-red solution which on dilution yields a flocculent yellow precipitate. The filtrate, after evaporation with alcohol to expel

nitric acid, leaves a light brown gum which deposits small crystals of oxalic acid on standing. The gum was not obtained in a sufficiently pure condition for analysis.

The yellow compound precipitated by water from the nitric acid solution of D was washed, dried, and purified by dissolving in acetone and precipitating with benzene. It forms an amorphous, yellow powder readily soluble in alcohol and acetone, but insoluble in ether, benzene, light petroleum, and chloroform. Analysis yielded the following results:—

(1) 0.1191 grm. gave 0.2218 grm. CO_2 and 0.0568 grm. H_2O .

(2) 0.2172 grm. gave 0.1117 grm. CO_2 and 0.1002 grm. H_2O .

(3) 0.1716 grm. gave 7.8 c.c. N_2 at 19.5°C . and 737.8 mm.

(4) 0.1551 grm. gave 7.1 c.c. N_2 at 17.8°C . and 741.2 mm.

whence $\text{C}=51.48$, 52.07 ; $\text{H}=5.30$, 5.13% ; $\text{N}=5.04$, 5.41% .

$\text{C}_{11}\text{H}_{13}\text{NO}_6$ requires $\text{C}=51.8$; $\text{H}=5.1$; $\text{N}=5.4\%$.

Attempts to determine the molecular weight of the substance resulted in failure.

Summarising the results of this investigation, as far as the oxidation products of rubber are concerned, it may be stated:—

(1) That when purified rubber in considerable mass is exposed to the action of oxygen at a temperature of 85°C for a period of six months or thereabouts, with frequent extraction of the soluble surface oxidation products, at least four substances are produced: (A) a light reddish-yellow transparent viscid resin of neutral character, insoluble in water but soluble in most organic solvents and possessing a composition agreeing with the formula $\text{C}_{16}\text{H}_{26}\text{O}_3$; (B) a fawn-coloured amorphous solid of feebly acidic character, insoluble in water but soluble in most organic solvents and possessing a composition agreeing with the formula $\text{C}_6\text{H}_8\text{O}_2$; (C) a brown, amorphous substance insoluble in water and in practically all organic solvents, but soluble in dilute alkalis; its composition agrees with the formula $\text{C}_{11}\text{H}_{16}\text{O}_4$; (D) a reddish-brown amorphous substance insoluble in water, in alkalis, and in all organic solvents with the exception of formic acid, which attacks it chemically, converting it into new substances; its composition agrees with the formula $\text{C}_9\text{H}_{14}\text{O}_2$; concentrated nitric acid attacks the substance yielding oxalic acid, a water-soluble gum, and a yellow insoluble powder of the formula $\text{C}_{11}\text{H}_{13}\text{NO}_6$.

The literature on the subject is not extensive. Spiller, in 1865 (*J. Chem. Soc.*, 18, 41), published an analysis of a resin-like substance extracted from perished rubber, and showed that in composition it approximated to the formula $\text{C}_{30}\text{H}_{38}\text{O}_{10}$, while Herbst has stated (*Ber.*, 1906, 39, 523) that by passing air for several days through a boiling solution of Para rubber in benzene, two products are obtained: (A) a yellow, amorphous solid, produced in small quantity only, soluble in benzene but insoluble in petroleum, and agreeing in composition with the formula $\text{C}_{10}\text{H}_{16}\text{O}_3$; (B) a brownish-red syrup readily soluble in petroleum and agreeing in composition with the formula $\text{C}_{10}\text{H}_{16}\text{O}$.

The results recorded in the present paper tend to show that the oxidation of rubber is in reality a process of considerably greater complexity than has been suspected hitherto. While Herbst's observations indicate the formation of what appear to be two simple addition products, it would now appear that at least four distinct compounds are produced, none of which exhibits any simple relationship to the original molecule of rubber, whether this latter be formulated in accordance with the views held by Harries (*Ber.*, 1905, 38, 1195) or with those put forward more recently by Pickles (*J. Chem. Soc.*, 1910, 97, 1085).

It should be noted that Herbst's description of the two compounds which he represents by the formulæ $C_{10}H_{16}O$ and $C_{10}H_{16}O_3$ respectively, accords roughly with that of the two compounds A and B to which the authors assign the respective formulæ $C_{16}H_{26}O_3$ and $C_6H_9O_2$. The difference in composition is, however, considerable. In the compound which he represents as $C_{10}H_{16}O$, Herbst found an average amount of 80.14% carbon (a figure which is not by any means in good agreement with the suggested formula) as compared with 72.09% found by us in the compound which we represent as $C_{16}H_{26}O_3$. In the more highly oxidised compound, Herbst found 65.54% carbon as against the mean figure 63.55% found by us in the compound which we formulate as $C_6H_9O_2$. The lower percentages of carbon found by us suggest a more exhaustive oxidation.

DISCUSSION.

MR. H. L. TERRY noticed that the behaviour of vulcanised rubber on oxidation was quite comparable to that of raw rubber, both extracted and unextracted, and that no volatile sulphur compounds were detected. It was generally accepted in commercial circles that vulcanised rubber decayed more readily than unvulcanised rubber. He had in his possession a skein of elastic thread of raw Brazilian Para rubber 32 years old which was absolutely sound. The problem was to produce a vulcanised sample capable of withstanding atmospheric conditions to a greater degree than was possible at the present time. He had also a sample of vulcanised rubber, in appearance resembling shellac, which could be ground up in a mortar, and forming the hard yellow resin mentioned in the paper. There was at present no really practical knowledge of the composition of this substance and no solvent had as yet been discovered. Both Burghardt and Spiller had made experiments with it and failed to achieve any satisfactory results. Spiller's resin contained 27% of oxygen—a higher figure than shown in any of the authors' analyses. The conclusion to be drawn from the paper seemed to be that the panacea had not yet been discovered for preventing oxidation in vulcanised rubber goods as ordinarily manufactured.

MR. PAYMAN asked whether the authors had detected any hydrogen peroxide in the gaseous product of the oxidation process, thus indicating that auto-oxidation took place in the presence of the normal oxidation.

MR. ROWELL hoped that the authors would continue their researches with regard to balata containing its natural resins, as it was of great importance to manufacturers to know the rate of decay of balata when put to work on an ordinary textile belt. Balata contained a certain proportion of saponifiable resin, but when put to work a larger proportion of resins which saponified could be obtained owing to the process of oxidation.

MR. MORGAN asked if the author had conducted experiments with ozonised air as well as oxygen.

THE CHAIRMAN said that he had observed that if very thin sections of indiarubber threads, for instance, when perished, were treated with colouring matter such as an alcoholic solution of methylene blue or magenta, the oxidised portions took up the colouring matter and the good rubber did not. Minute bubbles of air were observed inside the threads and around each of these was a distinct colour. Some of the thread sections showed stratified layers of colour when thus treated. Again, it was curious that if ozonised air were passed over an unstretched rubber thread it appeared to have little or no action upon it, whereas a stretched thread perished almost immediately.

MR. PEACHEY, in reply, said that the proportion of oxygen found by analysis in substances B and D

was 29%, a higher figure than any previously quoted. To take one analysis, the actual percentages of C, H, and O were 63.19, 8.29, and 28.52 respectively. Hydrogen peroxide appeared to be formed in small quantity during the oxidation and was detected by rinsing out the flask with water after the completion of the oxidation and applying to the aqueous extract the titanous sulphate and the potassium iodide tests. There appeared, however, to be a trace of levulinic acid amongst the products and possibly a little levulinic aldehyde peroxide might be formed, and thus account for the peroxide reaction. It was undoubtedly the case that peroxides were present in an aqueous extract of the material. All the main products of the oxidation were insoluble in water with the exception of the small amount of substance indicated on the left-hand side of the table. It might be possible in the future to conduct further experiments with regard to balata, but it must be remembered that research work on the pure balata hydrocarbon was hardly comparable in its results with that on the technical material. All the experiments had been made in approximate darkness, and the effect of light had not been investigated. It was not possible to draw any conclusions from the experiments with regard to atmospheric oxidation of rubber at ordinary temperatures. A higher temperature had been employed in order that oxidation might proceed at an observable rate. There was apparently no advantage in storing rubber in darkness under water. No experiments had been made with ozonised air, though the effect of ozone on a solution of rubber in chloroform had been studied by Harries with results which were familiar to all rubber chemists. When rubber was stretched it broke after a few minutes' exposure to the action of ozone, whereas if unstretched the action was not so quickly manifested.

Newcastle Section.

Meeting held at Bolbec Hall on Wednesday, January 16th, 1918.

MR. HENRY PEILE IN THE CHAIR.

COKE AS A FUEL FOR THE BLAST FURNACE.

BY G. W. HEWSON.

The substitution of coke for charcoal or coal as a blast-furnace fuel introduced an era of increasing productiveness from the blast-furnace, resulting from greater height of furnace which could be used, and increased pressure of blast permissible. The increase in the height of the furnace was largely due to the ability of the coke to withstand the crushing action of the descending materials much better than coal or charcoal, and thus reach the tuyères before which there is the greatest combustion.

The chief object of the use of fuel in a blast furnace is the production of intense local heat in the vicinity of the hearth; by its combustion it also acts as a reducing agent.

Quoting from Forsythe, the characteristics which make a fuel desirable for use in a blast-furnace are:—

- (1) A well-developed cell-structure. A porous fuel will present more surface to the action of the blast than a dense one, and therefore facilitates and hastens combustion.
- (2) Firmness—a fuel which changes its shape in the furnace, either through being

crushed by the weight of the accompanying materials, or through softening under the action of heat, is undesirable, as the filling of the interstices of the charge with fine or pasty material impedes the current of gases and hampers combustion.

(3) Purity—other conditions being equal, it is evident that the higher the fixed carbon the more efficient the fuel. The non-carbonaceous material develops no heat, but forms a slag which absorbs heat in melting.

Whilst charcoal is more desirable than any other fuel for its readiness to combine with the oxygen of the blast, and also for its purity, the impossibility of the supply meeting the demand rules it out of consideration—except in a limited way—as a blast-furnace fuel.

In a general way coke comes next in efficiency and value to charcoal, and is more desirable than coal, hence its almost universal adoption. The demand for coke became so great that thousands of beehive ovens must have been built with the sole object of supplying coke for blast-furnaces, and so good was this coke that at a later stage of coke-making many managers preferred beehive coke to by-product coke. Beehive ovens, however, had their limitations, and it was these which led to a change of practice in manufacture. Coking small coal in such ovens was only possible as long as the coal possessed sufficient agglutinative power to produce coke at temperatures within the limits of what beehive ovens were capable of withstanding.

In about 1855 the demand for coke commenced to increase and beehive ovens began to be superceded on account of the increasing scarcity and price of coal suitable for coking in this type of oven. The first uses to which retort ovens were put were to produce coke from coal low in volatile matter and agglutinative power, to obtain a greater yield of coke, and to increase the production of coke by shortening the coking period. Successive improvements have been effected, such as improvements in the arrangements for controlling the admission and circulation of gas and air in the flues in such a way as to produce higher temperatures and to distribute the heat uniformly along the whole length and height of the oven walls; adapting the dimensions of the ovens and the coking time to suit the nature of the coal; improving the firebrick work so as to allow the side walls to be diminished in thickness, in order to give a more rapid conduction of heat to the ovens. Later, modifications have from time to time been made to collect various by-products from the so-called waste gases expelled from the ovens.

Variations in the rate of coking and temperature have been made to improve the yield of by-products. There is a limit to which this can safely be carried without deterioration in the quality of the coke, and thus adversely affecting the production of iron from the blast-furnace. The latter, though unchanged in principle for several centuries, still remains the most complex in principle and most difficult to operate of any metallurgical apparatus, and while there are so many factors involved which can only be regulated within comparatively wide limits, it is not only desirable but also very necessary that all factors affecting the operation of the furnace which can be controlled and regulated should receive very serious attention.

Among the chief of these is the physical and chemical composition of the coke used. The lack of regularity and uniformity in the quality of the coke is a very serious handicap to the producer of pig iron. The fundamental principle underlying successful operations at the blast furnace, is that the composition and quantity of the slag, together

with the temperature of the smelting zone and the hearth determine the quality of the iron produced. These in turn are decided principally by the quality of the coke used as fuel, and by the distribution of the burden. In the past the production of pig iron from the blast furnace has been largely a question of charging the materials in the quantities found by experience to give a good marketable product. Fortunately the range of composition of saleable pig iron has been somewhat wide, and it has been possible to grade the iron made, and send supplies to customers according to fracture or analysis of the finished product. Modern requirements, however, demand from the blast furnace a product within narrower limits of composition, and of greater uniformity than has hitherto been obtainable. Again, these demands are such that a slight modification in the furnace working may have a very detrimental effect upon the operations; in other words, the margin of safety of working is much restricted. Any irregularity in the blast furnace reacts more readily upon such iron than upon iron higher in silicon, as the margin of reserve heat is less, and the product is in danger of becoming useless, and at the same time the furnace becomes distinctly cold, and serious harm may result in producing "off grades" of pig iron.

The principal source of heat in the furnace is the coke charged, and any variation in its composition or heat-giving capacity at once affects the heat in the smelting zone and hearth of the furnace. With reservations which will be considered later, the available carbon of the coke is a measure of its heat-producing capacity.

Steel furnaces have in the past taken pig iron containing from 2% to 3.5% Si, largely because thereby they were more assured of an iron sufficiently low in sulphur, to ensure a steel within the limits allowed. With the introduction and development of the basic open-hearth process, lower silicon content in the iron is the practice—about 1%—while as the sulphur can be partially eliminated in this process, the maximum limit of sulphur can be raised above what is demanded for hæmatite iron for the acid process. To ensure a good output of steel, however, it is essential that the sulphur content must not be excessive. Using iron with 1% Si and below, it is more difficult to keep the sulphur regularly below 0.1% and also more difficult to control the furnace operations, than when making foundry iron or iron for the acid steel process.

With the extraordinary demand for various distillates to-day, coke is in danger of losing its supremacy, and of taking a very secondary place in the list of products obtained from the distillation of coal. There appears a wide field for research in the direction of ascertaining the best temperature and rate of gasification for each class of coal used, as coals from different depths and different districts have not the same coking powers.

The physical composition of the coke is no less important than the chemical character. The most important physical characteristic is the hardness or density, which is the measure of its resistance to abrasion or crumbling. A good hard coke will also produce more intense heat than soft coke. The efficiency of heat utilisation in a blast furnace depends upon the concentration of heat, and this is best produced by a hard fuel.

Hardness test. To make a hardness test, an average sample of coke is crushed in a Baxter crusher, or on a plate with the usual hammer, to pieces from $\frac{1}{2}$ in. up to 1 in. across. This is sieved through a $\frac{1}{2}$ -in. mesh, and that remaining on the sieves is dried at 100° C., and 28 lbs. weighed and placed in a drum or rattler 26 in. diam. and 16 in. depth, together with a dozen cast iron balls $1\frac{1}{2}$ in. diam. The drum is given 1000 revolutions in about 1 hour, and the coke is withdrawn and

sieved on an $\frac{1}{8}$ -in. mesh; that remaining on the sieve is weighed, and calculated to percentage of the original weight. This percentage is given as the hardness number.

For example, if 27 lb. 2 oz. remain on the $\frac{1}{8}$ -in. sieve and 14 oz. passes through, the hardness is $27.125 \div 100 \div 28 = 96.9$.

Available carbon. The chemical composition of the coke resolves itself ultimately into the amount of "available carbon" which it contains. The value of the fuel is also affected by the physical nature of the coke. By the term "available carbon" is understood the quantity of carbon present in the coke in excess of that necessary to melt the slag formed by the ash and sulphur of the fuel, together with the limestone used to flux them. According to Forsythe the ash requires double its weight of limestone, and the sulphur three and one half times its weight to form slag. The slag formed requires 25% of its weight of carbon to melt it. When this is deducted from the fixed carbon the remainder is called "Available carbon." For example, a coke containing fixed carbon 86%, ash 10%, sulphur 1%, will require $(2 \times 10) + (3.5 \times 1) = 23.5\%$ of its weight of limestone. With 55% of limestone passing to slag, then $10 + 1 + (23.5 \times 0.55) = 23.9$ lbs. of slag per 100 lbs. of fuel. $23.9 \times 0.25 = 5.97$ lbs. of carbon to melt the slag. $86 - 5.97 = 80.03\%$ "Available carbon." Each 1% of ash affects the available carbon by 0.5% and each 0.1% of sulphur affects it by 0.08%.

TABLE I.
Beehive cokes.

No.	Ash.	Sulphur.	Fixed carbon.	Available carbon.	Hardness.

All the analyses have been given on the dried coke in order to make them more comparable. The influence of appreciable variation in the amount of moisture contained in the coke can easily be understood.

Cokes Nos. 20 to 28 inclusive were made from

differing classes of coal in the same set of ovens, and as nearly as possible under similar conditions, each extending over one week, and afford a striking example of the need for studying the correct temperature and period of coking for each class of coal.

Cokes below 94 hardness caused serious trouble in working and resulted in the furnaces scaffolding or hanging and getting decidedly cold. Cokes below 85% available carbon when in use have caused irregularities if burdened at the same rate as others, evidently from shortage of sufficient heat-producing carbon. The best all-round cokes are Nos. 16 and 29.

These tables emphasise the desirability of using one class of coke exclusively upon one furnace if sufficient supplies are available. Where such a procedure has been adopted more uniform results in the working of the furnace and the quality of the iron have been observed. For example, the difference in the quantity of available carbon between cokes 16 and 17 is equivalent to 2 cwt. per ton of iron. Consider a furnace working regularly and satisfactorily on coke No. 16, changed to No. 17 without any account being taken of its inferiority, the result would be equivalent to taking off the burden 2 cwt. of coke per ton of iron made, a change no one controlling furnaces would knowingly make; yet such is the practice at many blast-furnace plants of mixing in the same bunker small parcels of coke from different ovens and different coals, that some such violent change as instanced above will take place.

The bad effect of soft coke is cumulative and proportionate to its softness, owing to its liability to crumble during handling between the ovens and the furnace bell, resulting in a large quantity of breeze and small coke being charged into the furnace, and also owing to the crushing of the coke in the furnace. Both these causes result in less available carbon reaching the tuyères than would be the case with harder material.

Sulphur. The function and behaviour of sulphur in the furnace have been exhaustively investigated by Wüst and Wolff in 1905; their conclusions may here be given:—"Contrary to the generally held opinion, the sulphur in the coke does not reach the level of the tuyères of the blast furnace without undergoing alteration, but a great portion of it is previously volatilised by the ascending gases, and is then largely absorbed from the gases by the descending charge, and in this condition arrives in front of the tuyères. Up to 800° C. the sulphur is principally absorbed from the sulphur-laden gases by the oxides of iron, while from 800° upwards the position is reversed and the lime becomes the chief absorbent of the sulphur."

Determination of moisture. The moisture in coke is all superficial and is in no way combined with the coke substance, hence coke cannot be crushed without losing moisture. It is a mistake to crush a sample as finely as is usual for coal or other minerals; anything up to 1-in. cubes should be taken, and say 1000 or 2000 grms. weighed out, and dried at any temperature between 100° and 200° C. Samples for moisture determinations should be dried as quickly as possible after taking, and should be kept in an air-tight container if necessary to convey them any distance.

DISCUSSION.

Dr. J. E. STEAD wrote that in his experience the densest and hardest retort carbon had to be used in order to produce the highest temperature in their small furnace for determining the melting point of firebricks, etc. With cold blast they attained to a maximum temperature of 1750° C., whereas ordinary coke of the porous variety would not give anything like that temperature, and charcoal, which was still more porous, gave a still lower result, so there seemed to be some doubt

whether hard, porous coke was best for giving the highest hearth temperatures.

Mr. G. WEYMAN said that it was a matter of great difficulty to get uniform coal from the pit. In one case he had tested each waggon of a train of 15 cars of coal from one colliery; great care had been taken in the sampling. The ash in individual waggons varied from 3% up to 21%, and the average of the whole train-load was about 10%.

Mr. E. F. KNOTT referred to the question of phosphorus, which was a matter of considerable importance to coke makers at the present time when low-phosphorus coke commanded an enhanced price.

Mr. A. SHORT remarked that coke suffered a great deal in transport. Users ought to see that it was carefully handled and not allowed to get crushed more than could be helped. He suggested that coke makers ought to establish a joint large-scale experimental plant where various coals could be coked in different ovens and under different conditions of coking. He asked what hardness in Mr. Hewson's determinations would be satisfactory.

Dr. S. H. PATERSON, referring to Dr. Stead's statement, suggested that the temperature attainable was probably dependent upon the depth to which surface combustion took place beneath the face of the fuel. Were this determined, it might explain the differing calorific intensities of various forms of carbon.

Mr. C. H. RIDSDALE said that the densest coke that could be produced was porous enough for blast furnace purposes. A big coke, like beehive coke, helped to keep the furnace very open, as now, more than ever, the tendency was to get small ores. With small ores and small coke, it was not possible to drive the furnaces. 18 cwt. of large coke would give better working and just as much effective heat as a ton containing 2 cwt. of dead small. In a particular furnace working (basic), where a large proportion of the material was reduced by solid carbon on the hearth, the coke consumption being 27 cwt. per ton of pig, an efficiency of only 2300 heat units per unit of coke was obtained. The loss of 1153 heat units, equivalent to $\frac{1}{2}$ cwt. of coke, was sufficient to reduce the quality of pig from open grey mottled to ordinary white—the former a perfectly good iron for steel-making, the latter unsuitable. That same $\frac{1}{2}$ cwt. difference in coke equivalent was equal to a reduction in quantity of iron produced of 0.8 cwt. in pig, the iron passing into the slag instead of being reduced and passing into the pig, and raising the slag for a quarter of an hour (the time it took to make a ton of pig) to a 2.41% iron content. The same effect could be produced by a variety of causes, such as leakage of water at the tuyères, drop in temperature of blast, badly calcined stone reaching tuyères, etc., and, amongst others, a drop in quality of coke used, due to more ash, and hence less carbon. In 1900 he had made some careful balance-sheets of heat received and consumed by blast furnaces with coke consumptions varying from 21 to 31 cwt. The data so obtained had constantly proved to be reliable in practice. They showed clearly that, however high the coke consumption, of the whole coke charged most of the heat yielded went in doing what might be termed "dead work"—work the effect of which was not apparent (effecting the necessary chemical changes, heating the escaping gases, etc.), and that it was only the small balance over what was necessary for those purposes—namely, a very small excess of heat—which, once the "dead" requirements were satisfied, produced the effects noticed on grade of iron. The effects of small variations of heat available were thus accentuated when they occurred in the hearth. Thus, in the case of a furnace using 27 cwt. of

coke, the heat produced by 21 cwt. was used up for purposes other than the fusion of slag and pig, and only that from 6 cwt. was used in the hearth for that fusion. Looked at in that light, one got a very different impression of the effect of $\frac{1}{2}$ cwt. of coke or its equivalent, for it equalled $8\frac{1}{2}\%$ of all used in the hearth. That explained why any drop in quality, either chemical or mechanical, abstracting so large a proportion of the heat from the hearth, told so heavily on the product. As to the size of the coke, the breaking from large to small pieces was not so important as the crushing to fine dust, which blew out into the flues and gave trouble in the dust-catchers and the flue-dust.

Dr. J. T. DUNN said a question arose as to what was meant by "hardness." He thought it was more a question of what had been termed "friability." He had always understood that the requirement in coke was that it should not, in passing down the blast furnace and rubbing about the walls, etc., produce fine coke, but that it should simply break up into smaller pieces—that, in fact, the ultimate portions of the coke should be hard, and that it was not quite so important that the block as a whole should be hard.

Mr. RIDSDALE remarked that it was not that the coke would not resist the static pressure. What was wanted was resistance to breaking up and crushing when coke was dropped first into the trucks, then into the bunker, and finally into the furnace, and then had several tons of heavy ore dropped on top of it.

Mr. HEWSON, in reply, said that he intended making modifications in his method of testing hardness of coke and hoped by this to get a sharper line of division between good and bad coke. At present he considered coke satisfactory if the hardness number was above 94. Gas coke would only give a hardness number of 90–92.

The CHAIRMAN said that washing coal prior to coking would no doubt improve the chemical composition, but he rather thought that it had not a beneficial effect upon the physical properties of the coke.

DR. R. M. CAVEN IN THE CHAIR.

SOLUBLE GLASS.

BY R. M. CAVEN, D.S.C. (LOND.), F.I.C.

Sodium metasilicate is readily soluble in water, from which it separates in hydrated crystals having the composition $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$. Such a silicate however, is of little if any commercial interest, the kinds of soda-glass in use for various purposes having a ratio of silica to soda by weight of at least 2 to 1, and frequently 3 to 1, or even more. In the former case the product is known technically as "alkaline silicate," in the latter as "neutral silicate."

These silicates are not chemical compounds, since they may contain silica and soda in varying proportions. They probably consist of solid, anhydrous solutions of the monosilicate, Na_2SiO_3 , or perhaps the disilicate, $\text{Na}_2\text{Si}_2\text{O}_5$, in excess of silica.

Glasses so rich in silica are not readily soluble in water; indeed, even when finely pulverised they dissolve but slowly and imperfectly in boiling water; and the larger the proportion of silica the less is the solubility.

It is necessary for soda-glass to be dissolved in water, *i.e.*, to become in reality soluble glass, before it can be technically effective. This is true whether it is to be employed in the well-known form of a viscous solution or in a solid state.

Soluble glass solution is at present prepared in either of two ways. In the first way finely divided silica, in the form of flint, infusorial earth, quartz, etc., is heated with caustic soda solution under a steam pressure of three or four atmospheres. At the elevated temperature thus attained by the alkaline liquid the silica slowly dissolves, and the dilute solution of soluble glass which results is subsequently evaporated to the desired consistency.

In the second, and probably more usual way, sodium carbonate, or a mixture of sodium sulphate and coal, is fused with the required amount of silica in a furnace at a temperature of about 1100° C. The result is a hard, transparent glass, which is broken mechanically, or else cracked by dropping it whilst molten into water, and is subsequently dissolved in water.

How this dissolution may be best effected has been the subject of much investigation, but the method which has survived and is employed at the present day consists in heating the broken glass with water under a steam pressure of about 5 atmospheres. The glass yields to this treatment with water at a temperature of about 150° C., just as silica does when heated similarly with dilute alkali; but the resulting solution is dilute, and needs to be evaporated considerably to obtain a solution of commercial utility; and, moreover, it cannot easily be evaporated to dryness because of the formation of a skin on the surface of the colloidal liquid as it becomes concentrated; and if this difficulty is overcome intumescence occurs later, so that what eventually results is a more or less solidified froth.

The preparation in the solid form of a soda-glass readily soluble in water is, however, very desirable, not only to save the difficulty and cost of carriage of the liquid solution, but because the solid itself would have very distinct uses. (See Henkel, Eng. Pat. 23,391, 1911, this J., 1912, 189, and R. F. Bacon, this J., 1917, 26, 11.)

Methods of preparing such a solid, soluble glass from the almost insoluble glass obtained by high temperature fusion have now been discovered (Spensley, Battersby, and Holmes, Eng. Pats. 11,959, 1914; 108,576, 1917; Caven, Eng. Pats. 106,247, 1917; 108,372, 1917; this J., 1915, 834; 1917, 712, 1007), and it is the purpose of this paper to explain the chemical principles underlying these methods.

Briefly, the processes consist in grinding the nearly insoluble glass either with water (Spensley, Battersby, and Holmes) or dry (Caven), and suitably heating the product, thoroughly mixed with a small amount of water, until a vitreous solid results, which dissolves readily and almost completely even in cold water.

This statement of procedure, taken in conjunction with the fact that agitating the same powdered glass with excess of hot water has little effect upon it, points to the conclusion that the quantity of water employed influences the degree of solution which takes place, and that in a sense opposite to what is usual. Ordinarily the larger the amount of solvent employed the more readily will a solid be dissolved; in the solution of soda-glass, however, excess of water hinders solution, and the reduction in the amount employed down to a certain minimum promotes it.

The following results show that this is the case. In these experiments finely ground neutral silicate was employed in which the silica-soda ratio was 2.91:1. This was shaken with water in the proportion of 1 of silicate to 1, 2, 3, 4, and 5 of water,

for 6 hours at atmospheric temperature. The bottle containing the 1:4 mixture was broken, but the solutions in the other bottles were found to be of the following relative strengths, much solid remaining undissolved in each case:—

Solid contents of equal volumes.

Glass: water.	SiO ₂ .	Na ₂ O.	Total.	SiO ₂ /Na ₂ O by weight.
1:1 ..	0.0754	0.0321	0.1075	2.35
1:2 ..	0.0346	0.0159	0.0505	2.18
1:3 ..	0.0263	0.0107	0.0370	2.44
1:5 ..	0.0140	0.0066	0.0206	2.13

SiO₂ Na₂O in original glass=2.91.

These figures plainly show that the concentration of the solution formed diminishes as the proportion of water used increases, and indeed the total amounts of solid matter in solution are found to vary almost exactly in the inverse ratio of the amounts of water employed. A further interesting point is brought out by the ratio of silica to soda in solution. This is considerably less than in the original anhydrous glass; that is to say, the glass has not dissolved as a whole, but there has been a preferential solution of soda, so that the glass remaining undissolved is relatively poorer in soda than the original glass.

Similar results were obtained when the same powdered neutral silicate was agitated with water in tubes immersed in boiling water, in this case for half an hour. The solutions were in each case filtered and diluted when cold to 100 c.c. Aliquot portions taken for titration and evaporation then yielded the following results:—

Relative strengths of equal volumes.

c.c. water per 2 grms. powdered glass.	SiO ₂ .	Na ₂ O.	Total.	SiO ₂ /Na ₂ O by weight.
10.....	0.0782	0.0288	0.1070	2.72
14.....	0.0535	0.0208	0.0743	2.57
18.....	0.0423	0.0164	0.0587	2.59
22.....	0.0340	0.0136	0.0476	2.52
26.....	0.0269	0.0115	0.0384	2.33

SiO₂ Na₂O in original glass=2.91.

The same diminution in solubility on dilution is observable here as in the experiments with water at atmospheric temperature; and the silica-soda ratio is also less than in the original glass, although a little higher, especially with the smaller amounts of water, than with the cold water.

In order to make a comparison between the solubility of the soda-glass and that of an ordinary sparingly soluble salt, quantities of purified calcium sulphate, weighing 2 grms. each, were shaken in the same way with amounts of hot water equal to those employed in the preceding experiment.

Five c.c. portions of each of the filtered solutions were then evaporated and ignited, and the following weights of anhydrous calcium sulphate obtained in the five cases: 0.0112, 0.0113, 0.0100, 0.0101, 0.0108 gm. Thus the solutions formed were of the same strength, irrespective of the quantity of water used, and the above amounts of calcium sulphate correspond to saturated solutions of the salt.

That the behaviour of soda-glass towards water is in marked contrast to that of a sparingly soluble salt which dissolves without chemical change, is strikingly manifest when the above results are shown in the form of curves (see fig.) Thus while the solubility of calcium sulphate, which is independent of the quantity of water used, is shown by a horizontal straight line, that of soda-glass is

represented by a curve which descends with increasing amounts of water. So it is clear why the glass cannot be dissolved in much water. And further, the soda-curve is less steep than the silica-curve, owing to the preferential solution of the soda.

From these results two conclusions may be drawn: first that if the glass is to be dissolved

effectively in water the minimum amount of water must be employed; and second that if it is possible for the glass to dissolve as a whole, without preferential solution of soda, this, too, will take place with the minimum amount of water.

A modification of the above experiments bears out these conclusions. If instead of being agitated with hot water, the finely divided glass is allowed to lie in a layer at the bottom of the containing vessel beneath the water, its particles gradually cohere to form a vitreous mass, and the supernatant liquid is found to contain silica and soda in the ratio in which they exist in the anhydrous glass, the solution having been gradually formed by diffusion from the vitreous product below it; and after sufficient time has elapsed the latter is found to be completely soluble in water in all proportions.

The supernatant water may be omitted; that is to say the powdered glass may be mixed with not more than enough water to cause it to vitrify when heated to a temperature approaching

100° C. for about four hours. The product is then a hard, tough glass which can be reduced to powder and dissolved in any proportion of water.

To produce this result sufficient water must be mixed with the finely powdered, anhydrous glass to make a thick paste in which every particle is thoroughly wetted. From 2 to 3 parts by weight of water to 8 parts of the glass is a convenient proportion. If more than this proportion of water is used and the mixture is agitated during heating the resulting hydrated glass will not be perfectly solid, but slightly viscous like pitch; whilst if the mixture remains quiescent during heating the product will be in two layers, the upper of which will be a viscous fluid, and the lower a vitreous solid. Eventually, by the addition of more water, a limit will be reached beyond which, if the mixture is agitated, some of the glass will not become hydrated or be rendered soluble. If much less than the above proportion of water is used the glass particles will not be completely vitrified, but instead will form a caked mass, physically resembling sandstone, in which unchanged particles of the anhydrous glass are embedded in a matrix of the soluble, hydrated glass. Thus Henkel (Eng. Pat. 9730, 1898, this J., 1898, 763) mixed water with the powdered soda-glass in the proportion 1:6, and heated the mixture to 120° C. The result was an opaque mass which disintegrated and partially dissolved in water, but left behind much of the original glass unacted upon.

The following are the percentages of water, and residue after stirring with much hot water, found in a specimen of hydrated neutral soda-glass obtained by the above-described process (I.), together with the percentages of the same components in the product obtained from the same powdered glass by the Henkel process (II.).

	I.	II.
Water, %	23.2	16.2
Insol. matter, %	0.9	24.9

The reason for the above difference lies chiefly in the deficiency of water used in the second case, though partly also in the high temperature employed in the early stages of heating. The amount of water used should be sufficient to leave not less than 20% in the finished product, and the initial temperature should be about 70° C. Very little water then evaporates though the final temperature should rise to 100° C.

The conditions for the production of a hard, vitreous, soluble, hydrated soda-glass are thus the following:

(i.) The anhydrous glass must be pulverised sufficiently; it should pass through a sieve with 50 meshes to the linear inch in the case of the neutral glass, though a sieve of 20 meshes suffices for the alkaline glass. The powder should not be exposed to the air unduly, since it readily absorbs water and carbon dioxide. This is especially the case with the alkaline silicate.

[Some of the pulverised neutral silicate which had been kept in a screw-top bottle for about twelve months was found to contain 18% of water and 4% of carbon dioxide. It did not yield a good hydrated product.]

(ii.) Sufficient, but not too much water must be mixed with the pulverised glass; the weight of water should be between 25 and 38% of the weight of glass.

(iii.) The mixture, which may be placed in a flat cake tin, coated inside with lime, and loosely covered, should be heated sufficiently, but not too strongly. The initial temperature should be about 70° C. and the final temperature, after about four hours' heating, should not exceed 100° C.

[Since no temperature above 100° C is required, there is no need of superheated steam, or heating under pressure.]

The product may be ground, and is practically permanent in the air. A coarsely ground specimen, which had been kept for twelve months in a loosely corked bottle, contained 22.3% of water, and left 5.5% of insoluble matter when stirred with hot water. Some of it was kept over sulphuric acid in a desiccator for seven days. The loss of weight in this time was 4.2%, and the insoluble residue had risen to 6.8%.

Theory of the process.

The pulverised glass which has passed through a suitable sieve will contain particles of varying size, and the finer of these will dissolve first when the powder is heated with water. As the solution produced increases in concentration the temperature may be gradually raised without risk of aqueous evaporation, and so the coarser particles are gradually acted upon until the whole of the glass has been dissolved.

The resulting vitreous solid is to be regarded not simply as a hydrated form of soda-glass which is soluble in water, whilst the anhydrous form is nearly insoluble; but rather as a solution of the glass which, because of its concentration, is solid rather than liquid, and which is diluted rather than dissolved by being mixed with water, so as to produce a liquid instead of a solid solution. The hydrated glass is eminently colloidal; like glue itself, it does not form a saturated solution with water, there being no limit to its solubility.

When, as an alternative, the anhydrous glass is ground in the presence of water, the process of solution commences during the grinding, because the finest particles thus produced dissolve in the water even when cold, or but slightly heated by the absorption of the heat of friction. The process of solution is then completed by subsequent heating.

The preferential solution of soda which is demonstrated by the figures given above shows that the action of water on the soda-glass is one of hydrolysis. The sodium hydroxide thus produced in solution then dissolves some of the silica, and the resulting sodium silicate is in turn hydrolysed with the liberation in solution of hydrated, colloidal silicic acid, together with sodium hydroxide. The free alkali then dissolves more silica, and so on, until the whole of the glass has been changed from an anhydrous solution of silica and soda into an aqueous solution of colloidal silicic acid and sodium hydroxide. That an indeterminate amount of silicate of soda, in which silica and soda are chemically combined, exists both in the anhydrous and aqueous solutions does not affect the general theory of the process.

It will be plain from these considerations why as little water as possible should be present. Much water so dilutes the hydrolytic sodium hydroxide as to retard or inhibit its solvent action on the silica, so that the glass does not dissolve to any extent.

The theory of the process of solution may be formulated thus:

Let $\text{Na}_2\text{O} \cdot x\text{SiO}_2$ be the composition of the anhydrous soda-glass and $\text{SiO}_2 \cdot n\text{H}_2\text{O}$ that of the soluble, hydrated silica or colloidal silicic acid; and let it be supposed that the silica cannot be hydrated directly by the water, so that $\text{SiO}_2 \cdot n\text{H}_2\text{O}$ must necessarily be a product of the hydrolysis of a sodium silicate. Then the following reactions occur:

The process is repeated x times till the last term is eliminated, and solution is complete.

By adding, the following equation is obtained to represent the final result:

The colour of anhydrous and hydrated soda-glass.

Anhydrous, fused sodium silicate, whether neutral or alkaline, is transparent and generally pale green; occasionally it is the colour of amber—especially in the case of the alkaline silicate—but this colour appears to be due to extraneous impurity—probably ferric oxide—dissolved by the glass whilst molten. The green colour, like that of common bottle glass, is due to iron oxide in the sand and other material employed in the manufacture of glass, the compound formed in solution being ferrous silicate. The amount of iron present may be judged roughly by the depth of the green colour; it is commonly about 0.1%. When this glass is ground with water, or mixed with water after being finely ground in the dry state, the cream formed is at first white, but on standing gradually becomes greyish-violet. When the powdered glass has been heated with water so as to convert it into the soluble form, the colour of the finished vitreous product is found to be dark grey or brown. Indeed the colour and appearance of the hydrated glass closely resemble those of agate or flint.

The cause of this remarkable colour-development may be briefly dealt with. The colour is attributable to the iron present; indeed, apart from extraneous dirt, which has been carefully excluded, there appears to be no other cause for the colour. But the question arises why so deep a colour should appear. If the iron were completely oxidised from the ferrous to the ferric state during the hydration process, the delicate green would be exchanged for a yellow colour. If, however, the ferrous iron were oxidised to hydrated ferrous-ferric oxide, a deep colour would be produced. Atmospheric oxidation of ferrous hydroxide, precipitated from a ferrous solution by alkali, is very familiar. The precipitate, which is first white, passes through a greenish-black stage before it becomes rust-coloured. Precipitated ferrous phosphate shows an analogous phenomenon. In fact, depth of colour is associated with the presence of both ferrous and ferric iron in the same molecule, as for example also in ferric ferrocyanide or ferrous ferricyanide (*vide* Hofmann and Resenschek, *Annalen*, 1905, 342, 364).

That the partial oxidation of ferrous to ferrous-ferric hydroxide accounts for the deep colour developed in hydrated soda-glass appears very likely from the fact that when a concentrated aqueous solution of the glass is made, the somewhat turbid liquid, containing a small amount of insoluble matter in suspension, is grey, contains both ferrous and ferric iron, and is bleached by heating and drawing air through it, whereby the iron is oxidised to the ferric state.

Incidentally, since flint and agate so closely resemble this glass in colour and appearance, it may further be suggested that these minerals owe their colour to the same cause.

Since the colour of hydrated soda-glass is due to the presence of iron, it might be prevented by the use of iron-free materials in the manufacture of the glass.

It is probably not practicable, however, to secure materials quite free from iron, or entirely to exclude it during manufacture, and glass with only a very pale green tint still develops considerable colour during hydration.

Some alkaline silicate was made from a sample of Fontainebleau sand, such as is used in glass:

manufacture, and which contained only 0.03% of iron, together with some commercial sodium carbonate, containing a trace of iron. The green tint of the resulting glass was very pale, but the hydrated glass prepared from it was decidedly grey. Moreover it is obviously useless to counteract the green tint by manganese oxide, since this would only aggravate the colour on hydration.

Fortunately, however, the dark colour of the hydrated glass is not detrimental when the latter is to be employed for making solutions of soluble glass, since the liquor may be bleached by oxidation, and then all the iron is found in the small sediment that remains after settling, from which a clear and practically colourless solution can be withdrawn.

DISCUSSION.

Mr. W. A. RICHARDSON considered that Dr. Caven's work threw light upon the problems of flint in at least two points. In the first place his contention that the colour was due to ferrous-ferrie oxide was in agreement with such evidence as was available. Most authorities (*e.g.*, James Geikie and Prof. Sollas) stated that the flint colour was due to the presence of carbonaceous matter. If any carbon were present in the flint only a minute quantity had ever been proved, and this was, judging from the amount present in other rocks coloured black by carbon, quite incompetent to produce the intense black coloration of flint. On the other hand analyses given by Hardman (*Sci. Trans. Roy. Soc. Dublin*, 1878, p. 85) for Irish cherts showed 1.15% Fe_2O_3 and 0.15% FeO . This he gathered from Dr. Caven's investigations was ample for the purpose. Another point which struck him as interesting was the hardening of the artificial glass on loss of water. This might have some parallel in the weathering of flint. In the analysis quoted above the loss on ignition was 1.43%. In the weathering of flints, particularly in the Thames Valley gravels, he had noticed the following points:—

(A) A probable loss of water accompanied by a gradual leaching out of the iron content. The flint turned to paler and paler shades of grey and was finally completely bleached. It also became more porous as shown (1) by the fact that it was opaque, not transparent or translucent as the black flint would lead one to expect, and also (2) by its subsequent absorption of red hydrated ferric oxide, in which the gravels abound. This absorption gave the flint a secondary brown to red staining.

(B) The flint became harder probably owing to the loss of water from solid solution. This point was illustrated by the use of fresh chalk flints in S.E. England for building, in preference to those picked from the surface of the land, because these latter were too hard to dress (*J. A. Howe, "Geology of Building Stones,"* p. 328).

(C) The weathering action often etched the surface, giving it a pitted appearance showing that a portion of the flint was less resistant to weathering agents.

Mr. H. DROOP RICHMOND asked if it was not possible to prepare sodium silicate free from iron by the use of precipitated silica. In regard to Dr. Caven's scheme illustrating the mechanism of gradual solution, he wondered if some advantage would not accrue, if in place of sodium hydroxide and hydrated silica the existence of two distinct sodium silicates were postulated, one rich in soda, the other poor, relatively to silica. In fact he wondered whether the alkali was as free from the silicic acid as the scheme suggested. One of the conventional tests made use of in the technical examination of commercial sodium silicates was a determination of the free alkali that remained in solution after precipitation with barium chloride. Had Dr. Caven any knowledge

as to the composition of barium silicate produced under such conditions (alkaline precipitation)? When determining sulphate in water analysis he had obtained high results by direct precipitation with barium chloride, because the silica in solution had been precipitated by the barium. The composition of the barium silicates need not of necessity be similar, but certainly they possessed more than academic interest.

Mr. J. M. WILKIE, referring to Mr. Richmond's remarks, expressed a preference for the postulation of a number of silicates of varying contents of sodium and silicic acid. In such concentrated solutions hydrolytic dissociation could not be anything like complete, but, of course, this did not in any degree invalidate the value of Dr. Caven's schematic treatment. It appeared to him that the composition of barium silicate would vary with the conditions of precipitation and that the ratio of barium oxide to silica would be affected by adsorption and the presence of the ions in solution.

Dr. NAEF said that it was possible to obtain silica free from iron by dialysis and that such a product might be utilised in an attempt to make a sodium silicate free from iron.

Mr. CALAM described an experiment in which coal gas had been burnt in a glass vessel; during the combustion of the gas a layer of iron oxide had been precipitated on the glass. The presence of the iron oxide was attributed to the decomposition of iron carbonyl present. He also referred to another experiment in which powdered window glass had been heated with a small quantity of water under pressure, the resulting product having been a solid mass of glass. The suggestion was put forward that possibly quartz had been formed from a mineral like geodite in a similar way.

Mr. LEWIS stated that at the present time, large quantities of silicon were being manufactured, by the electric furnace process for the purpose of generating hydrogen by treatment with caustic soda, and suggested this method as a possible means of obtaining pure sodium silicate.

Dr. HEDLEY said that he had made soluble glass on a large scale but had never succeeded in rivalling the pale green specimens shown. He remarked on the very minute traces of impurities required to produce coloration, referring to the work of Verneuil, who had shown in 1911 that the colour of sapphires was due to traces of titanium oxide—from 0.03 to 0.06%—and who had made artificial sapphires containing minute amounts of iron and titanate oxides. Again, the colour in diamonds was due to even more minute traces of iron, titanium, and manganese, and since such deep colorations were produced by mere traces it was not to be wondered at that very great difficulty was experienced in producing a colourless silicate, even when using pure quartz and sodium carbonate. In connection with the experiment described by Mr. Calam of treating window glass with water at a high temperature, he referred to the proposed process for the manufacture of potassium compounds, which was based upon the fact that feldspar on treatment with caustic soda at 270°–300° was changed into an artificial leucite (*this J.*, 1917, 1234). With regard to obtaining sodium silicate as a by-product in the production of hydrogen, he stated that the cost of preparing one cubic metre of hydrogen from silicon and caustic soda was 53 pence, from ferro-silicon 10 pence, and from water and iron 1.5 pence. Thus in order to be a commercial success the silicate resulting from the reaction would have to pay for the difference between 1.5 pence and 53 pence; so that as to whether its collection would "pay" seemed highly problematical.

Dr. CAVEN, in replying, said with regard to Mr. Droop Richmond's remarks that the difficulty

of obtaining a colourless sodium silicate would not be overcome by using iron-free silica, since commercial sodium carbonate contained traces of iron, and there was the probability of iron contamination from the crucibles employed for the fusion. He had prepared some alkaline silicate from colourless quartz and commercial sodium carbonate and the colour of the product was pale green, resembling that of the best commercial specimens. He saw no objection to the suggested alteration of the theory of the process of hydration, since the essential principle was unaffected thereby. Whether or not free sodium hydroxide was produced on hydrolysis might be a question of dilution; certainly it was formed in the presence of much water. Sodium metasilicate appeared to be hydrolysed in aqueous solution according to the following scheme:

$$2 \text{Na}_2\text{SiO}_3 + \text{H}_2\text{O} \rightleftharpoons \text{Na}_2\text{Si}_2\text{O}_5 + 2 \text{NaOH}$$

(Kohlrausch, *Zeits. physikal. Chem.*, 1893, 12, 773; Kahlenberg and Lincoln, *J. Phys. Chem.*, 1898, 2, 77). He could give no information on the properties of barium silicate. In reply to Dr. Hedley, he was surprised to hear of fused sodium silicate which was almost black. Undoubtedly the pale green glass was a commercial product.

PROF. J. W. COBB IN THE CHAIR.

MODERN METHODS OF SULPHURIC ACID MANUFACTURE.

BY G. L. MOSS.

The heavy chemical industry, in which this country has held her own, has of late years been inclined to rest on its laurels, and it needed the stimulus of war to arouse it to a sense of its inefficiency.

To take the case of the sulphuric acid manufacturer, how many could honestly answer "yes" to all the following questions:—

Are you getting all the available sulphur out of your raw material?

Are you getting the greatest possible output of acid per cub. ft. of chamber space?

Is your nitre consumption at an irreducible minimum?

Are your repairs also at a minimum?

Can your plant deal with any class of ore on the market without prejudicing your output and quality of product?

Are you getting the greatest possible output per unit of ground space?

It is gratifying to know that in this industry there have been many important developments during recent years, and the author thinks it will be of general interest to record the main lines on which these have been made.

The conventional method of erecting a sulphuric acid plant was to make the structural work of the towers and chambers entirely of wood. The chambers were supported by heavy stanchions and joists to which the lead was fastened by straps; the tops were usually left exposed to the weather, and sometimes the sides as well. As a rule, however, the sides were protected by a sort of matchboarding with gaps in the joints for air circulation. The tops of the towers housing the circulating tanks were similarly covered.

The towers were usually square in cross-section and the Glover was often packed with large lumps

of lava stone, flints, etc., the Gay-Lussacs with coke. Now for towers which are essentially scrubbers, both the shape and the packing were wrong. Owing to the timber employed in construction, however, round towers were not a feasible proposition, but during recent times more efficient means of packing were employed. Blocked or partially blocked Glovers were common owing to accumulation of dust and they could not be easily washed down. "Ratholes" frequently developed in the coke packing of the Gay-Lussacs, resulting in the gas traversing one side of the tower and the acid running down the other, with consequent loss of nitre. Many plants in this country to-day have only one Gay-Lussac tower. Lunge states that he has proved that coke in Gay-Lussacs has a reducing effect on nitrous gases. There are now many forms of patent packings on the market to-day, but in the author's opinion, good vitrified chequer brick for the Glover and rings for the Gay-Lussacs are the most satisfactory.

The fifty-second annual report of the Chief Alkali Inspector for the year 1915 (this J., 1915, 1011) states that of 338 Glover towers in the United Kingdom, 130 were packed with flints, 127 with bricks, 28 with bricks and flints, 23 with rings, 16 with bricks or tiles and rings, 8 with tiles, and 6 with bricks and tiles; and of 440 Gay-Lussac towers, 269 were packed with coke, 58 with bricks, 43 with glass, 25 with rings, 17 with tiles, 10 with bricks and tiles, 8 with rings and coke, 7 with bricks or tiles and coke, 4 with rings and tiles, 3 with Lunge-Rohrmann tiles, and 1 with balls.

The old chambers naturally varied in size with the output of the plant and they frequently attained a length of some 120 ft. The height usually ran from 15–20 ft., and the cross-section was approximately square. A cubical capacity of anything up to 30 cub. ft. per pound of sulphur burned per 24 hours was allowed, though in recent times this has been reduced to from 12 to 20 cub. ft. Steam was used as a rule in the chambers, being introduced either at the top or ends—if the latter, frequently in a single jet. The trunks connecting the towers and chambers were square in section and braced with timber in a similar manner to the chambers. All this timber naturally rendered the plant a prey to fire, and several plants have been completely destroyed by this means. Apart from this danger the structure was very flimsy and prone to rot. The wood under the influence of acid and heat would perish, and unless constantly renewed when this happened, was liable to collapse under wind pressure. This is no uncommon occurrence, and several chambers have been literally blown down. The method of strapping the lead was very rigid and left no room for movement under expansion and contraction. Tearing of the straps on the chamber sides resulted.

On the older types of plant hand burners were usual, burning lump ore. With this type of burner the sulphur in the burnt ore is usually high, the gas of uneven composition, and labour costs high. There is not much trouble with dust as a rule. On the introduction of mechanical burners burning fines, sulphuric acid makers began to realise what dust troubles are. The mechanical burner gives much greater efficiency in abstracting the available sulphur from the ore and a constant gas composition. At the same time much less labour is necessary for a given output. The great disadvantage is dust, and when burning some of the low-grade Spanish and Portuguese ores the trouble is very serious. No dust chamber ever built can extract it all. It is in such an extremely fine state of division that it defies all attempts at settling it out and rapidly turns the Glover acid into a thick porridge, blocking the packing at the same time. This impedes the denitration of the strong nitrous vitriol and increases the nitre con-

sumption. The usual method is to flush the tower down with chamber acid from the overhead feed tank, which always upsets the working of the chambers for 6 to 8 hours, with further loss of nitre. Efforts to overcome these troubles by increasing the size of the dust chambers, introducing filtering materials, etc., have not been successful. Too large dust chambers sometimes mean insufficient heat for the Glover tower. The author hopes to show how these difficulties have been successfully overcome, whereby practically water-white Glover acid, absolutely free from dust, has been produced.

For purposes of comparison one or two more features of the older plants are worthy of mention. On hand burners, only one fan is necessary and this is situated as a rule between the two Gay-Lussacs (where two are employed). This was usually steam driven and consequently subject to varying speeds, causing unequal gas composition by varying the draught. Very often no fan at all was used, the outlet being connected with a stack. Wind speed and direction here had its influence on the draught. Even with suitable chambers it was impossible to get a low chamber space owing to the varying conditions imposed by the appliances then in use. The essence of intensive working is constant gas composition and nitre supply in the first place.

The old means of elevating the circulating acid was by intermittent eggs—egg-ended castings holding two or three tons, which were filled and blown up by operating the valves by hand.

One of the principal features of the plant to be described, is the method in which de-arsenication is effected. Before describing the details of this system, it will perhaps be of interest to outline briefly the old method with its attendant difficulties.

The most generally applied process is that in which hydrogen sulphide is employed; the arsenic being precipitated as arsenious sulphide. The gas is usually generated by the action of weak sulphuric acid on ferrous sulphide. The gas is passed up a short tower, down which the acid is fed, afterwards running to the filtering apparatus, where the liberated arsenious sulphide is separated. The acid goes to the concentrators and the sulphide mud is periodically dug out of the filters, after being washed with water. Another form of apparatus is that in which the contact between the gas and acid is effected by a rotating splashing device. Whatever apparatus is used, however, the process suffers from a grave disadvantage, viz., that effective de-arsenication and filtration can only be carried out at an inconvenient dilution of the acid, between 100°—112° Tw. (sp. gr. 1.50—1.56), which is considerably below the strength of chamber acid made at most English works. At higher concentrations the acid is decomposed by the hydrogen sulphide according to the equation:—

The precipitated sulphur is exceedingly difficult to filter and causes trouble in the subsequent concentration. Any nitre present in the acid consumes hydrogen sulphide and thus increases the cost of the process. It is evident, therefore, that to dilute Glover acid of 146° Tw. (which holds the most of the arsenic) to a convenient strength for de-arsenication is a troublesome and costly process, both as regards the bulk of liquid to handle and the fuel required to reconcentrate it. As a rule it is not de-arsenicated and is sold with all its dust and arsenic. If it is de-arsenicated at all it is not usually diluted, and what is regarded as the lesser evil, i.e., precipitated sulphur and high hydrogen sulphide consumption, is allowed to take its chance. If the arsenic content is high it

has to be passed more than once through the apparatus.

The plant to be described is designed and erected by Messrs. Simon-Carves, Ltd., of Manchester. Even at first glance, there is a pleasing contrast between the new and old systems. The neat and compact brick buildings at once create a striking comparison with the old timbered structure, with its rambling outline and towers stuck at different corners. Closer examination reveals the great improvements effected from a chemical engineering standpoint.

In the first place the plant is quite weatherproof and practically fireproof (insurance only costs about 1s. 6d. per cent.) The only timber employed in its construction is for the chamber floors and the distributor platform. The method of suspending the lead (which will be later described in detail) and its protection from the weather, combined with the extra cooling effect obtained by the greater height of the chambers, contribute in an ideal way to intensive working and long life.

The whole chamber house is made up of a skeleton framework of steel and built in with 4½-inch brick suitably pigeon-holed to provide air circulation. A large glass louvre at the apex of the roof provides an exit for the warm air and ample illumination.

The burner house is of more solid brick construction and is well lighted and ventilated. It provides housing for the burners and dust chamber, the pyrites elevating machinery, together with the gas heater, and, in a separate room, the machinery for propulsion of the gases, compressed air pumps, etc. The towers are situated in a traverse of the chamber house and are all neatly arranged side by side.

The burners consist of a steel casing enclosing a series of firebrick arches swept by revolving arms which are actuated from a central vertical shaft. The special features of these burners are the following:—The shaft and arms are air-cooled, the air being supplied by a fan blast. The hot air, after leaving the top of the shaft, serves to dry the pyrites spread on a specially constructed floor, before being fed into the hoppers. The arms are held in place by an ingenious locking device which at the same time permits their easy removal and replacement. The burners are chain-driven from a shaft running alongside in a trench, each burner being provided with a clutch. A trip arrangement automatically unmeshes the drive in case of overload. Each burner has a rated capacity of 8 tons of ore per day with a 50% load variation either way. Only ½ horse-power is required to drive it.

The gases from the burner trunks, containing up to 10% of SO₂, are led into the dust chamber, where a preliminary settling of the dust is effected. They afterwards pass to the wash tower (instead of, on the old system, the Glover tower), where the dust is removed, together with most of the arsenic, by a copious flood of acid. By this means they are cooled down to little above atmospheric temperature. Final cooling, necessary for the elimination of arsenic, takes place in the filters placed in the open air. These are small leaden chambers packed with selected coke. The gas, now perfectly clean, only requires heating to be ready for the chamber process. Heat exchange is effected by passing it back through the dust chamber in contact with the hot gases from the burners, after which it traverses a gas heater, where a temperature of 350°—400° C. is imparted to it by a coke fire. On a works where waste gas is available this operation is most conveniently and economically conducted by that agency, the need of a fireman being dispensed with. The hot gas now enters the potting oven, similar in most respects to established practice. From this point the course through the Glover chambers and Gay-Lussac towers is precisely similar to other chamber

plants, but the gas possesses the great advantage of being absolutely free from dust.

The manner in which greater efficiency of chamber space and many conveniences in working are effected will now be described. The towers are circular in section; those working on hot gas, the Glover and wash tower, are suitably lined with heat-resisting brick and packed with vitreous chequer work. The Gay-Lussacs are ring-packed. The two former towers are provided with spacious ponds to facilitate cleaning, and these ponds are water-jacketed in order to preserve the lead. Even distribution of acid on the towers is ensured by specially-designed distributors. The leadwork of the towers is suspended from the joists carrying the distribution floor. The lead of the chambers is similarly suspended from the principals of the roof, by means of flat steel strips, covered with lead, and fixed at right angles to the chamber sides. These have the effect of gills and materially assist in the radiation of heat from the chamber sides. These gills are slung from a system of joists in the structural steel work. It will be observed that by this method of free suspension the leadwork is permitted to adjust itself to temperature change without tearing at straps, etc. The design of the tops of the chambers is of importance. Segmental in section and supported by curved gills, the shape is conducive to intensive working. If we accept the theory that the gases in the chambers have a spiral motion on a horizontal axis, it is obvious that this shape of top leaves no room for stagnant pockets of gas, as would one of square section. With their great height of up to 65 ft., and the above methods of securing rapid heat dissipation, these chambers can work at 6 to 8 cub. ft. of space per pound of sulphur compared with 11 to 20 cub. ft. on the wooden system. Some well-managed works of the latter type have been able to get down to 10 to 11 cub. ft., but only at the cost of great wear and tear in leadwork.

A device which contributes much to the efficiency of chambers, is the use of water sprays instead of steam. The water is supplied to the sprays at a pressure of about 70 lb. and enters the chambers in the state of a fine mist. Apart from the cooling effect, much better regulation of the "drips" is possible.

Another very efficient type of chamber is circular in section, and is, in fact, a tower, but unpacked. Suspended in a similar manner, even lower chamber space can be obtained—about 4 to 5 cub. ft. The earliest attempts at reduction in chamber space consisted in devices to cause greater interaction of the gases by increased surface contact whilst retaining the original shape of the chambers. Lead curtains in the chambers were tried, but as the metal was subject to no cooling action, they soon collapsed. Glass partitions were also tried, without success. Lunge towers were the most successful, but never attained extensive use in this country.

The Opl system replaces the chambers entirely with towers. This seems to be the ideal process, as very low "chamber" space is claimed for it—2 cub. ft. In practice, however, it is evident that it is still in an experimental condition as there is very much pumping of acid round the towers, with consequent power consumption. Loss of nitre, when it sets in, occurs with great rapidity and unremitting scientific supervision is necessary.

Water-cooled chambers of conical shape are now being tried, with which a chamber space of 1 to 5 cub. ft. is claimed.

An important item on a sulphuric acid plant is the addition of nitre or nitric acid. Most English works use nitre applied by means of a "potting oven," which is a miniature nitric acid plant. The nitric acid evolved from regular small charges mingles with the hot gases entering the Glover tower. There is much to be said for

this system as regards its effect on the working of the chambers, but it has the drawback of being wasteful of acid (27—32% free acid in the nitre cake), and moreover if the charges are at frequent intervals (as they should be) it occupies practically one man's whole time each shift.

Continental practice favours the direct use of nitric acid. This is usually fed down the Glover tower in conjunction with the nitrous vitriol. In the author's opinion this system has very little to recommend it. Its one great advantage is that a "falling off" in the chambers can be more quickly remedied than by any other means, inasmuch as a large quantity of nitric acid can be almost instantaneously added just at the place where it is needed. That this is greatly in its favour, anyone familiar with intensive working will freely admit, as it is an accepted fact that the lower the chamber space the quicker is the nitre lost. This is but natural owing to the increased velocity of the gases, which becomes still greater with deficient nitre. Unless an excess of nitre is applied at once, the loss increases rapidly owing to the reaction working round into the back chambers and thus preventing re-oxidation. The effect of this soon shows itself in the strong nitrous acid coming from the first Gay-Lussac, the nitric oxide content of which rapidly falls. As this acid goes back to feed the Glover tower, it is obvious that on arrival there it will contain insufficient nitre to convert the sulphur dioxide in the gas, so that the addition of extra nitre must be kept up until the nitric oxide content of the first Gay-Lussac acid is again normal and the lower strength nitrous vitriol is worked off. Otherwise a vicious circle is set up and the plant goes from bad to worse. In cases of this description the nitric acid fed down the Glover tower is of great value, as it is possible to get sufficient in to convert all the sulphur dioxide, even supposing the acid from the first Gay-Lussac contained no nitric oxide. This is not usually possible in a potting oven (which is also much slower in effect) as in very big charges the nitre cake will have to come out of the pots "uncooked," i.e., containing undecomposed sodium nitrate.

On a well-managed plant, however, the above state of affairs is only of infrequent occurrence, and under ordinary circumstances the nitric acid system becomes an intolerable nuisance. Nobody likes handling carboys of anything, least of all nitric acid. These must be hoisted to the top of the Glover tower and emptied into the feeding pot or siphoned out. Both are objectionable, as the apparatus used must be of earthenware or glass, neither of which materials is safe in the hands of the ordinary workman. Breakages are liable to cause fires through the acid coming in contact with the wood flooring.

On a plant making 140 tons of B.O.V. per week, the consumption of acid is only about 1 gallon per hour. The adjustment of such a comparatively minute feed is no small matter of difficulty, and the very position of the apparatus (at the top of the tower) renders it liable to neglect. A further drawback is that the strength of the acid is liable to variation, whereas that of nitre is very consistent.

Another practice, which is not to be commended for obvious reasons, is that of feeding a strong aqueous solution of sodium nitrate down the Glover tower in case of a bad shortage. Sodium nitrate sprays are sometimes employed in a small first chamber where the acid is to be used for superphosphate—the sodium sulphate produced being of no consequence. When nitric acid was first employed it was usually fed into the chambers. The devices employed were various and need not be described here. The practice has been abandoned owing to its destructive action on the lead

and tendency to produce a high nitre content in the bottom acid.

In the author's experience the best method is a combination of the nitric acid and potting systems. The former is only used in cases of necessity, and the method of introducing it eliminates the drawbacks described in connection with feeding down the Glover tower.

In the first place a standard strength of nitrous vitriol is determined, which at a given feed, is known to be sufficient to meet the gas from the existing load on the plant. We will assume that this strength is 12 c.c. of nitric oxide per c.c. of acid. The quantity of nitre introduced at the potting oven is arranged to maintain this same figure in the strong nitrous vitriol from the first Gay-Lussac tower, which, of course, should have the same quantity of acid feed as the Glover tower. In the case of something occurring which causes the plant to "fall off," or, in other words, create a tendency for the reaction to work round to the back chambers, the steps taken to right things are these:—The amount of sulphur dioxide in the burner gases is temporarily reduced (for a few minutes only is enough as a rule). If the position seems to warrant it, an addition is made in the potting, but not to the extent of causing the nitre cake to be discharged uncooked. In the meantime tests taken on the Gay-Lussac acid will show a gradual decrease in nitric oxide, very often preceded by a sharp rise of short duration. This acid is allowed to accumulate in the bottom tank and made up to standard figure with nitric acid before sending up to feed the Glover tower. By this means the apparatus for elevating the acid to the Glover tower also elevates the nitric acid, and an acid of absolutely constant strength is fed down the tower. The reaction becoming normal again soon allows the strong nitrous vitriol to resume its ordinary strength, when the addition of nitric acid ceases.

By this method a minimum of acid is used: the handling of it is reduced owing to its only having to be lifted the height of the low level strong nitrous tank into which it is emptied from a suitable platform. Moreover the plant is rapidly "brought round" and a great saving in nitre consumption effected. The evil of too much nitre, which is so fatal to the lead of the chambers, and so liable to occur by the Glover feed method, is entirely avoided.

An outline of a new method of introducing nitric acid to the chambers has recently been published. Under the auspices of the Ministry of Munitions one or two large manufacturers have experimented with an ammonia oxidation plant for this purpose and good results are said to have been achieved. Further details will be awaited with interest by the industry.

The acid plant described is driven entirely by electricity. Decentralised driving has been found to be the best in practice, though more expensive to instal. Compressed air is supplied to the automatic eggs at 70–80 lb. pressure from a belt-driven compressor, which is fitted with an automatic cut-off device enabling the pressure to be maintained within a few pounds of that desired. The entire plant takes about 35 horse-power. At present prices the cost of such a plant is certainly not more than the cost of a wooden one of the same chamber capacity. Based upon output, however, it is about 40% cheaper owing to greater capacity per cubic foot of chamber space.

De-arsenication by this method costs about 2s. per ton of acid less than by the ferrous sulphide process, and much less if gas heating is available.

The chamber and Glover acids are practically water-white. It may be said without fear of contradiction that Glover acid made by this process is cleaner than that produced by any other plant using pyrites fines in mechanical burners. All the

dust and arsenic usually present in Glover acid is concentrated in the wash acid, which only amounts to 3–5% of the total output. The actual amount varies with the nature of the ore employed.

Concentration.

The concentration of sulphuric acid is a wide subject and full justice cannot be done to it in the scope of this paper. It would not be complete, however, without some mention of the broad lines along which development has taken place.

The older methods of concentration in glass and platinum vessels have now been practically abandoned. Concentration of chamber acid from about 120° Tw. (sp. gr. 1.6) is still effected in open lead pans on a large scale. Lead, if good quality, is not materially attacked by acid of under 150 Tw. (sp. gr. 1.75) and this method is very cheap where waste heat is available. Evaporation losses are extremely low.

The most rational, as well as the most economical, process of chamber acid concentration is in the Glover tower, whereby the weak acid assists the denitration of the nitrous vitriol and at the same time supplies part of the water necessary for the formation of sulphuric acid. Naturally there is no loss in this method. It is not possible always to work up all the chamber acid produced on a set in this way, neither is it possible to concentrate to high strengths. External plant must therefore be provided.

The cascade system is one of the most popular in use at present. By this method the weak acid is fed through a series of vessels of fused silica, or acid-resisting material of a metallic nature, of which there are several in the market. These basins are arranged in step formation whereby the acid flows from one to the other in its approach towards the hottest part of the flue and gradual concentration takes place. The lower portion of the cascade is covered in with blocks of lava stone or similar material and the acid vapours carried off under vacuum through a series of towers suitably packed, down which a stream of water is run, or more simply through a coke filter, which causes the condensation of acid fog. The fuel consumption on a plant of this description is about 25% of the weight of concentrated acid produced. This system is well adapted to gas firing, which can be very nicely adjusted and dispenses with the unavoidable disarrangement caused by the cleaning of the fire.

The upkeep of cascade plants is a heavy item, broken basins, etc., causing the acid to get into the brickwork of the flues. Distortion begins, and unless bad joints, etc., are made good at once, cold air is drawn in, with loss of efficiency. Unless the acid is very clean, iron is deposited in the basins and develops crusts, causing the acid to spurt. If the basins are of fused silica the crusts cause breakages; if of metallic alloy they are liable to burn out. It is of importance, therefore, that a clean acid be employed if upkeep costs are to be kept within reason. Bottomley gives details of a cascade plant of fused silica with beaker type preheaters (this J., 1917, 577).

The concentration of waste acids from nitration processes such as the manufacture of T.N.T. presents special problems owing to the presence of impurities. These impurities consist principally of iron, nitric and nitrous acids, together with considerable amounts of organic matter. One method of dealing with this acid is as follows: The feed acid descends a small earthenware tower packed with rings up which the hot vapours from final concentration are passed. The purpose of this tower is to preheat and denitrate the acid. The vapours pass on to the condensing system, whilst the acid flows to the first of a series of lead pans or preheaters where preliminary concentration up to about 140° Tw. takes place. Then follows

the usual cascade system where the concentration takes place up to 95%, after which the acid falls into a large cast iron pan placed over the furnace. The purpose of this pan is to bring the acid up to 97% strength and allow of easy cleaning of the deposited ferric sulphate which is thrown out of solution at this strength. The vapours given off from this pan are led to the preheating tower. Owing to the presence of nitric acid all the vapour pipes must be of earthenware.

The extreme discomfort to the operator of concentrating waste acid containing nitric acid is avoided if the acid be first denitrated by passing down an earthenware tower up which a current of slightly superheated steam at about 60 lb. pressure is blown.

The fifty-second annual report of the Chief Alkali Inspector for the year 1915 gives some interesting details with regard to cascade systems. Output per basin and details of condensers are analysed and tabulated.

A very successful plant which is specially suitable for the working up of large quantities (40—50 tons per day) of waste acid is the Gaillard tower. This apparatus is constructed of Volvic lava rings, and is about 40—50 feet high and 6—10 feet in diameter, according to output. The acid is fed down the tower (which is unpacked) in the form of a spray and meets the gases from a coke producer. The acid fumes are led away from the top of the tower into a smaller one where considerable quantities of weak acid are condensed and sent back with the feed acid. Final condensation takes place in a coke filter. The gases are drawn through the system by a fan placed after the coke filter. Upkeep in this type of plant is costly, but the output is high per unit of ground space occupied.

E. H. Armstrong (J. Ind. Eng. Chem., 1917, 9, 386—388; this J., 1917, 501) gives details of a tower method of concentration using quartz as packing and an oil flame for heat. The disadvantage seems to lie in the disintegration of the quartz; an instance of 50% being removed is quoted.

The type of concentrator usually supplied with the chamber plant described is a modification of the Kessler system. It consists of a coke producer with a capacity of at least 24 hours' working at maximum output. The hot air from this producer enters a "saturex" or saturator, travelling in a horizontal direction against the acid flow. The gas is deflected on to the surface of the acid by barriers placed at right angles to its path. The height of acid can be controlled by a weir placed in the outlet spout to the cooler. The gas, laden with acid vapour, after leaving the saturator, passes upwards in a zig-zag course through six or eight plateaux down which the acid is fed. This recuperation preheats the feed acid and condenses the acid mist from the gas. The plateaux are provided with barriers to facilitate contact between acid and gas in a similar manner to the saturator. The gas leaves the recuperator at a temperature of about 120° C., traverses a coke condenser, where the remainder of the acid mist is absorbed, and then through a fan to the atmosphere.

The principal difference between this apparatus and the Kessler is in the plateaux. In the Kessler the recuperator is more like a fractionating column, the contact between gas and acid being made by serrated porcelain hoods. These have

the disadvantage of becoming blocked with iron salts, necessitating frequent cleaning if the acid is not very free from this impurity. The open type of plateaux employed in the plant described obviates this difficulty to a great extent.

The saturator and plateaux are constructed of vitrified earthenware blocks, the joints being made with special cement. The whole is covered with stout lead and presents a neat appearance. The coke consumption is about 19%. Care should be exercised that the volatile matter is low or the acid is liable to be discoloured.

DISCUSSION.

The CHAIRMAN remarked that it used to be said before the war that the production of sulphuric acid in a country might be taken as an indication of its stage of civilisation. That remark would be of sinister significance nowadays; but there could be no doubt of the great and increasing importance of the manufacture. He asked the author whether the type of burner described (the Moritz) could be modified so as to roast a form of sulphide in regard to which external heating was necessary.

Mr. H. ROYAL-DAWSON said that the point put by Prof. Cobb had also occurred to him with reference to the burning of zinc sulphide, and of refractory ores in general, and he would like to know the type of burner used for these. The largest amount of acid came from pyrites of course, but with regard to other materials he only knew of one successful burner—he thought it was the Harris furnace—which could be used for zinc sulphide. The problem had been studied on the Continent, and he thought it was for this country to take the matter up, by zinc manufacturers treating their ores for recovering the sulphur as sulphuric acid in ore roasting.

Mr. G. F. HUDSON said that in concentration the difficulty was not to work a system with fair efficiency when it was new; they nearly all worked very well for a time; but then either the material of construction began to fail, or the heat of gas and leakages began to break the system down, often after only two or three years. Had the plant described by the author of the paper had a sufficiently long trial to compare in that respect with cascade concentrators, Gaillard towers, and other systems? The difficulties began when the materials had become saturated with acid.

Mr. Moss replied that the matter mentioned by Prof. Cobb had been receiving a good deal of attention of late, but there were very serious difficulties to be contended with. The burning of low-grade zinc ores, with perhaps 25 to 30% of sulphur, required extraneous heating. The necessity for the employment of artificial heat complicated the matter from the chemical engineering standpoint very considerably. As to the short life of concentration plants, he agreed in general with Mr. Hudson, but the type he had described had an exceptionally long life. He knew one Kessler type plant which had been working for something like ten years, and he thought it was practically as good as ever. Lava stone was liable to disintegration, but the material he had spoken of was not so liable, provided it could be obtained without flaw. Gaillard towers also had direct contact with the acid and gas, and they suffered from decrepitation, but he thought this type had on the whole proved to be satisfactory.

New York Section.

Meeting held at Chemists' Club on Friday, January 18th, 1918.

MR. JEROME ALEXANDER IN THE CHAIR.

PRESENTATION OF PERKIN MEDAL TO DR. A. J. ROSSI.

After some introductory remarks by the Chairman,

Mr. F. A. J. FITZGERALD gave an account of Dr. Rossi and his work, in which he mentioned that Rossi was educated in France, and came to New York in 1859. For some years he was engaged in engineering and surveying work, and was subsequently employed as chemist to the Boonton Iron Works. It was here that Rossi first became interested in the subject of titanium, the ores used in the blast-furnaces being magnetites containing from 1 to 2.5% or more of titanic oxide, and he made a close study of the problems connected with the smelting of titaniferous iron ores. This work, however, bore no fruit at the time, and it was not until several years after he had left metallurgical practice that owing to a lawsuit in connection with the Boonton Works, he became recognised as an expert in that particular field.

In 1890 he was consulted in regard to the smelting of the titaniferous ores of the Adirondacks, and since that date he has devoted most of his time to titanium. During his investigation of these ore deposits he found that in two small blast-furnaces which had been run between 1840 and 1858, excellent iron had been produced by adding large quantities of lime and silica to the charge, producing a silico-titanate slag—a practice adopted successfully also at Stockton-on-Tees with ores containing up to 35% TiO_2 . The objection to this process was the large quantity of slag produced, and Rossi made a series of experiments with the object of replacing silica by titanic oxide in normal blast-furnace slags. As a result of these experiments small blast furnaces were built to treat the ores in question, and the success of these paved the way for the commercial utilisation of these ores.

Rossi's work on the smelting of titaniferous iron ores had convinced him that titanium had a beneficial effect on iron and this led him to the belief that an alloy of iron and titanium would be of value in the manufacture of iron or steel. Experiments confirmed these views, and in 1899 electric furnaces were built at Niagara Falls, in which considerable quantities of ferro-titanium were manufactured and used for testing purposes. These tests bore out all his anticipations, but it was many years before he succeeded in convincing iron and steel makers of the fact, and even now the scepticism has not been entirely abolished.

In the early days of the use of titanium it was chiefly employed in rail steel, but recently it has been applied in a number of other directions. An instance of the beneficial effects of titanium is found in the results of 155 heats representing the production of 9000 tons of rail steel; when no titanium was used only 36% of the steel came within the specified limits, while with increasing amounts of titanium the following percentages passed:—0.053% Ti, 43%; 0.077% Ti, 81%; 0.10% Ti, 100%.

After a short congratulatory address, Dr. W. H. NICHOLS presented the Perkin Medal to Dr. Rossi.

Dr. Rossi, after expressing his appreciation of the honour conferred upon him, added some further details of his work, as follows:—

My experience at the Boonton blast-furnaces convinced me that the presence of titanium dioxide to an average of 1.50% TiO_2 in the ores which we were smelting, and of some 2 to 2.50% of TiO_2 in the slags, had had no effect on the working of the furnaces, or on the behaviour of the slags as to fluidity and fusibility, so much so that I even ignored its presence, considering it as so much additional silica in the ores. In 1894, at the New York Car Wheel Works, Buffalo, in a small furnace of a capacity of three to four tons a day, I melted, without admixture, titaniferous iron ores from the Adirondacks, containing 15 to 18% TiO_2 and 55 to 56% metallic iron, and the slags as run from the furnace contained 25–30% TiO_2 , and some 15 to 18% silica, with lime, alumina, and magnesia as bases, magnesia having been recognised by me as an essential constituent of the slags to ensure the best running. Within the last two years, Mr. Bachman has smelted similar titaniferous iron ores in one of the large blast furnaces at Port Henry, making some 15,000 tons of a superior pig iron with an economy of fuel per ton of pig metal smelted.

The titaniferous ores of the Adirondacks are magnetic, associated with ilmenite (FeTiO_3). They are, like almost all titaniferous ores, low in phosphorus and sulphur, some as low as 0.017% P and 0.02% S, with 55 to 56% metallic iron and 1.50 to 2% SiO_2 . The iron smelted from them is an ideal open-hearth steel. Tests made in many foundries of such pig metal added to ordinary pig iron in certain proportions have shown an increase of 29½% in strength over cast iron not treated and an increase of 4% over cast iron treated with nickel.

However much value titaniferous ores may have, alone or in mixture with other ores, as blast-furnace stock, their use for making alloys of iron or copper with titanium for the treatment of cast iron, steel, copper, or copper alloys has opened a new and more important field of applications in metallurgy.

In about 1900 I started making ferrotitanium at Niagara Falls in an electric arc furnace; the furnace itself, made of a masonry of graphitic materials, formed the cathode, and a carbon electrode, movable vertically in the cavity of the furnace, constituted the anode. A mixture of the titaniferous material and the carbon required for the reduction of both the titanium and iron oxides properly comminuted, was then charged gradually into the furnace as the current was turned on. When the relative proportions of the TiO_2 and the iron oxide in the titaniferous material were such as to produce an alloy higher in titanium than desired, some scrap iron was charged with the mixture to dilute the alloy, so to speak. I made in this manner alloys containing from 10 to 25% Ti or more, but practice in steel and other works has shown that an alloy containing some 15% Ti is best suited for most purposes.

Whenever the presence of carbon in the ferro-carbon-titanium was considered objectionable for special applications, I reduced the titaniferous materials by the aluminium bath process. Instead of using a mixture of finely powdered aluminium and titaniferous materials as in the Goldschmidt's Thermit process, the aluminium I used for the reduction of the oxides was melted in the electric furnace and the titaniferous materials (omitting the carbon) charged directly into the bath of aluminium. In such cases I used preferably TiO_2 as rutile, in order to avoid using the aluminium which would have been required for the reduction of the iron oxide of the ore, charging scrap iron with the rutile to dilute the alloy to the content of titanium desired. In this manner I made ferrotitanium containing only from 0.18 to 0.50% C, and by reducing the amount of scrap iron added, I was able to make ferrotitanium containing as much

as 80 to 85% Ti. Titanium is very hard and brittle so that as such it has no particular use. The alloys of titanium containing 75 to 85% Ti. or even less, are white like silver and scratch glass and even quartz deeply.

The aluminium bath process is of a more general application. If into the aluminium bath a tungstic ore containing iron oxide is charged, a ferro-tungsten is obtained free from carbon. I have made thus 85% tungsten alloy. By using manganese ores I was able to make in the electric furnace 85 to 88% ferromanganese free from carbon, and by using chromic iron, a ferrochrome containing about 80% Cr and free from carbon.

By adding to a bath of steel or to cast iron a ferrocarrbon-titanium containing some 15% Ti the bath of metal is cleansed from dissolved or occluded gases such as oxygen and nitrogen and also of such oxides of iron generally present in steel, especially in Bessemer steel made by the pneumatic process. When air is blown through the molten pig iron, the titanium of the alloy combines with the oxygen to form TiO_2 , with the nitrogen to form titanium nitride, and the iron oxide is reduced to iron by the titanium and the carbon; the titanium then combines with the oxygen to form TiO_2 , and the slag, carrying with it the titanium dioxide and nitride, rises to the top of the ingot or ladle: the TiO_2 renders the slag more fluid and fusible. A slag collected at the top of an ingot and containing 6.5% TiO_2 had a melting point of 1290° C. By adding enough TiO_2 to such a slag as to have in the slag some 13% TiO_2 , its melting point was lowered to 1190° C.

For the deoxidation of copper and its alloys such as bronzes, brass, manganese or aluminium-bronzes I have made a copper-titanium containing any percentage of titanium, though 10 to 15% appears most suitable. The titanium of such an alloy acts, as in steel, as a scavenger of the copper bath. I have also made aluminium-titanium containing 45% Ti for seasoning aluminium-bronzes. These alloys are made in the same manner as ferrocarrbon-titanium or ferro-titanium in the electric furnace. For copper-titanium, TiO_2 and aluminium are charged into the furnace in a bath of copper. For aluminium-titanium, the TiO_2 is charged directly into the bath of aluminium. The reaction of aluminium on oxides being exothermic, much less current is required for the reduction proper.

I have also carried out experiments in smelting titaniferous ores in admixture with phosphoric ores, even to the extent of obtaining a pig iron high in phosphorus. I used phosphoric ores containing as much as 1.50% to 2% P_2O_5 , even adding apatite to the mixture so as to obtain a pig iron as high in phosphorus as possible. Contrary to what might have been expected, the pig metal containing 0.40% Ti and from 2.50 to 3.50% P had the strength and the rating of fair No. 1 or No. 2 pig iron. This suggested treating phosphoric pig metal, generally weak and close grained, with ferrotitanium so as to incorporate a certain amount of titanium in it. The results were very encouraging.

If a ferrotitanium, practically free from carbon, made by my aluminium bath method, preferably as high in titanium and low in iron as possible, is heated with hydrochloric acid, in which it dissolves readily, a fine violet solution of a ferrous-titanium chloride is obtained. The double chloride contained about 40 to 50% $TiCl_3$, the balance being ferrous chloride. I have been able to bleach successfully and without injury cotton, silk, and wool by digesting them in this diluted violet solution at boiling temperature. During the operation, especially as the temperature approached the boiling point, TiO_2 was precipitated, thus showing that the chlorine must have been set free and combined with the ferrous chloride to form

ferric chloride, the chlorine generated acting in the nascent state without even appearing as free chlorine in the solution.

The fact that titanic oxide was precipitated from one of its compounds by these organic matters suggested to me the possibilities of precipitating this compound from others of its compounds by vegetable or animal organic matters, and the results were very remarkable. If to a solution of titanic sulphate, $Ti(SO_4)_2$, is added an aqueous extract of vegetable or animal substances (leaves, green leaves, sawdust, tannin, wood pulp, wood-pulp liquor, horse chestnuts, beans, etc.) and the liquid boiled for a short time, TiO_2 is precipitated and when calcined is obtained as a soft, smooth, flour-like, pure white powder requiring no mechanical pulverisation. If the titanic sulphate solution is precipitated by ammonia or caustic soda and boiled, and the TiO_2 calcined, the product is granular and buff-coloured.

This method of preparing the smooth, white oxide finds a direct application for the production of a white titanic pigment, a product which our company is to manufacture on a large industrial scale. Calcined titanic oxide possesses the property of covering when used as paint material alone or in mixture with other paint pigments. Its superiority on this score, when prepared with proper oils, over white lead or zinc white is remarkable, and in addition TiO_2 pigment is not attacked by sulphurous gases and is stable under climatic and atmospheric influences.

Titanic oxide, obtained as a gelatinous titanic acid, $TiO_2 \cdot 2H_2O$, and dried at 100° C., has the property of fixing colouring matters, like that of alumina. It can be prepared by known methods but the one I have studied is much more economical, as I can obtain it from a waste product of some of our manufactures. In that state it dissolves readily in oxalic acid, yielding a titanium oxalate which can be used in the same manner and for the same purposes as potassium titanium oxalate, which is much more difficult and costly to make.

Some of my work has been in an entirely different direction. I have used for purposes of artificial production of cold, instead of liquefied gases such as sulphur dioxide, carbon dioxide, or ammonia, a binary liquid composed of one moderately volatile liquid containing in solution the vapours of a much more volatile liquid. In ice-making and refrigeration the volatile liquids are charged in a special vessel, the refrigerator being immersed in a bath of uncongealable liquid so-called, such as a strong solution of sodium or magnesium chloride, or glycerin; or alternatively the liquid is caused to circulate in a tank in which cans containing the water to be frozen are immersed or circulated through pipes in the cellars of the brewery or store-room. By relieving the pressure of the volatile liquid on itself, at ordinary temperature, by means of a double-acting pump run by any power (steam engine or other), the liquid boils and by its latent heat of evaporation cools the refrigerator contents. The vapours entering the pump are compressed in a condenser cooled by circulating water, liquefied again under this pressure and cooling, and combined again, reforming the original volatile liquid, which is returned by proper devices to the refrigerator, rendering the operation continuous.

One of the binary liquids I used for machines erected in breweries and cold storages was ether containing sulphur dioxide in solution. Ether will absorb its own weight of SO_2 , showing but a very few pounds of pressure (5 to 6) per sq. in. at 90° F. By using such binary liquid instead of sulphur dioxide, for instance, when the mixed vapours enter the compressor to be compressed and discharged into the condenser, ether liquefies first, being cooled by the circulation of water

around the condenser, absorbing anew the sulphur dioxide and causing the pressure in the compressor and condenser to reach the figure it would have reached had sulphur dioxide alone been used, thus saving on the mechanical power required.

The other liquid I used was sulphur dioxide, which can absorb some 5 to 10% of its weight of carbon dioxide. In this case, the same advantages as with the other binary are secured but to a much greater extent. Carbon dioxide boils at about -100° F., and the pressures required to liquefy its vapours are considerable.

MR. JEROME ALEXANDER IN THE CHAIR.

TECHNICAL APPLICATIONS OF NEPHELOMETRY.

BY PHILIP ADOLPH KOBÉ.

The method known as nephelometry is based upon the measurement of the brightness of the light reflected by a cloud—in other words, by the particles in suspension—very much as in an ultramicroscope. The intensity of the light reflected is a function of the quantity of suspended particles, when other conditions are constant.

The principle of the nephelometer can best be shown by a diagrammatic sketch, shown in the accompanying figure. Let A and B represent

tubes containing a precipitate in the form of a suspension, and L represent a strong light which throws its uniform beam on tubes A and B at right angles; then *a* and *b* will be the light in the eye-piece due to the reflections from the two suspensions. If tube A, for example, contained distilled water and the instrument were perfect, no light at *a* would be visible. As soon as the smallest amount of suspension is produced in the tube A, light is obtained in *a* in approximate proportion to the amount of suspended matter. This light *a* is never measured absolutely, but is always matched at *b*, which is that reflected by the precipitate from a standard solution—a known amount of the substance to be determined dissolved in a known volume.

The matching of the two lights could be done by changing the standard solution step by step until it would be exactly similar to the unknown. In practice this would be tedious, and therefore instruments were designed to eliminate this in whole or in part.

Work with the nephelometer should always be conducted in the dark. Probably the greatest source of error connected with nephelometry or colorimetry, however, is practically an instrumental one. Most diaphragms or openings at the top of the eye-pieces, even in the best instruments, are too large, but by putting a small diaphragm of the size of a pin-hole over the optical centre, equal illumination of both sides of the field can be obtained.

The chief requisite for making nephelometric

clouds or colloidal suspensions, and for keeping them as such for definite time, is that the substance be in a dilute solution, usually not stronger than 100 mgrms. per litre. Clouds produced by one part in 500,000 of liquid may be determined quantitatively. In some cases one part in 2,000,000 can be easily determined.

If the precipitate to be examined is highly coloured and remains in suspension, it is best determined colorimetrically; if slightly coloured, it is best determined nephelometrically. The precipitate must be colloidal, in the form of a suspension. Certain solutions of protective colloids can be used, such as egg albumin and soluble starch, which cause crystalloids and partly colloidal precipitates to remain in suspension long enough for the application of this method.

The number of possible applications of nephelometry is too large for consideration here, and therefore a few representative estimations have been chosen, viz., three inorganic and three organic determinations; the estimation respectively of ammonia, phosphorus, calcium, acetone, oils and fats, and, finally, proteins.

Estimation of ammonia. S. S. Graves has developed a sensitive nephelometric reagent for ammonia: 80 grms. of sodium chloride is dissolved in 130 c.c. of water and 100 c.c. of a saturated solution of mercuric chloride, and 70 c.c. of a saturated solution of lithium carbonate (1.0%) is added and the mixture filtered. By means of this reagent one part of ammonia can be detected in 160 million parts of water.

For every 10 c.c. of ammonium sulphate solution 15 c.c. of a 0.003% solution of starch will keep the suspension from agglutinating and settling for about an hour. The standard solution contains 9.43 mgrms. ammonium sulphate, which is equivalent to 2.43 mgrms. ammonia, or 2.00 mgrms. nitrogen per litre. When precipitated with 5 c.c. of reagent the resulting suspension is put into both cups of the instrument.

If the left cup is placed at any convenient height and the other cup moved up or down until the light in the eye piece, coming from both tubes, is equal, the height on the right is rarely, if ever, equal to the height set on the left side. The reading on the right side will be denoted as the standard reading. If in place of the standard on the right other solutions of ammonium sulphate of different strength are used a series of corresponding readings is obtained, and these are plotted in the form of a curve.

When the instrument changes so that re-standardisation is necessary, a nephelometric formula may be used, but it is simpler to adjust the height of the solution on the left side (the one used as a tare) so that the original reading for the standard is obtained, and therefore the original curve is applicable.

In making estimations of nitrogen, 0.1 gm. of the substance to be examined is heated in a Kjeldahl flask with 20 c.c. of concentrated sulphuric acid, and a little mercury or mercuric oxide as catalyst, diluted and made up to 500 c.c. To 5 c.c. of this solution is added 5 c.c. of N/1 sodium hydroxide and then, drop by drop, the same solution until it is neutral to litmus paper. The solution is then diluted to 200 c.c. with ammonia-free water, and a 10 c.c. portion is treated with 15 c.c. of 0.003% starch solution and precipitated with Graves' reagent (5 c.c.) and matched against 10 c.c. of standard solution (containing 2.0 mgrms. of nitrogen per litre) similarly treated. From the reading and the curve we can find out at once the percentage of nitrogen.

Phosphorus. The reagent developed by Pouget and Chouchak* (a nitric acid solution of strychnine and molybdic acid) produces a very sensitive

* Bull. Soc. Chim., 1909, 5, 104; 1911, 9, 649.

reaction with phosphates, being capable of detecting one part of phosphorus in 20 million parts of water. As the precipitate is slightly yellow and remains in suspension for a long time, the authors have recommended it as a colorimetric reagent, but really the estimations were turbidimetric, i.e., they measured the absorbed light of the suspension.

On studying this reaction, Egerer and Kober found that it was not constant or quantitative, and that the reagent gradually became yellow and deteriorated, probably because of the action of nitric acid. On substituting hydrochloric for nitric acid, the solution not only remained practically colourless for an indefinite time, but was stable and gave quantitative and constant results.

To prepare the modified solution, 150 grms. of sodium molybdate is dissolved in 250 c.c. of water and 100 c.c. of hydrochloric acid (1:1) and 150 c.c. of strychnine sulphate solution (2.0%) added slowly with shaking. Protective action in addition to any produced by the strychnine does not seem to be necessary. The reagent is so sensitive that ordinary filter paper must not be used for filtering the reagent. A solution of potassium phosphate containing 0.003 mgrm. per litre shows the reaction very plainly, i.e., one part in 333 million.

For the determination of phosphorus in cast iron, 2 grms. of borings is dissolved in 100 c.c. of 1:3 nitric acid by boiling. After cooling under the tap the solution is made up to 100 c.c. and 5 c.c. boiled for 2 minutes with 5 c.c. of concentrated sulphuric acid. This mixture is then diluted to 100 c.c. and filtered through a dry filter paper which has been washed with acid, and 25 c.c. is again diluted to 100 c.c. 10 c.c. is now treated with 35 c.c. of N 2 hydrochloric and precipitated with 5 c.c. of reagent. On matching in the instrument with a standard containing 5 mgrms. of $\text{K}_2\text{H}_2\text{P}_2\text{O}_7$ per litre the percentage of phosphorus can be obtained from a curve made similarly to the one described for ammonia.

Calcium. Lyman's nephelometric reagent for calcium is prepared by boiling 4 grms. of stearic acid and 0.5 c.c. of oleic acid with 400 c.c. of 95% alcohol, boiling, adding 20 grms. of ammonium carbonate in 100 c.c. of hot water, boiling, cooling, and adding 400 c.c. of 95% alcohol, 100 c.c. of water, 2 c.c. ammonia solution (sp. gr. 0.90), and finally filtering. A solution of calcium oxalate in nitric acid containing 0.2 mgrm. of calcium per litre (one part in 5 million) gives a decided reaction with this reagent.

For the estimation of calcium in milk, 10 c.c. is diluted to 100 c.c. with distilled water. Five c.c. of this mixture is then treated with 15 c.c. of 6.5% trichloroacetic acid, which precipitates the proteins, and filtered. The calcium is now precipitated as oxalate by McCradden's method,* redissolved, and the calcium determined nephelometrically after precipitation as soap. 20 c.c. of standard calcium oxalate solution (dissolved in nitric acid) containing 0.4 mgrm. of Ca is poured into 50 c.c. of Lyman's reagent and gently shaken. This cloud is used for matching an unknown treated in a similar manner. Here, as in the other estimations, only a few circumventions are necessary to eliminate interfering substances. In this precipitation oleic acid acts as a protective colloid; a small amount delays the agglutination for hours.

Acetone. Marriott has applied the extremely sensitive Scott-Wilson reagent for the nephelometric estimation of acetone. The acetone in each case may be distilled from the original solution into the reagent or may be aerated† at room temperature into sodium bisulphite solution, and

then estimated nephelometrically. The composition of the reagent is given as: 10 grms. of mercuric cyanide, 180 grms. of sodium hydroxide, 1200 c.c. of water, to which 400 c.c. of 0.70% silver nitrate solution is slowly added and the mixture filtered. This reagent is sensitive to 1 part of acetone in 100 million. The standard and unknown solutions are precipitated by distilling into 50 c.c. of water and 15 c.c. of Marriott's reagent, 0.5 mgrm. of acetone, and finally making the solution or suspension up to 100 c.c. Standard solution if made with N/4 sulphuric acid so that it contains 0.5 mgrm. of acetone in 10 c.c. will keep for a few weeks at least. No additional protective colloid is added, as the organic nature of the complex is sufficient protection.

Fats and oils. Bloor has devised a nephelometric method in which the fat or oil is extracted with an alcohol-ether (3:1) mixture and then poured into water, when the fat or the oil separates in fine globules or suspensions. As little as 0.5 mgrm. of fat can easily be determined quantitatively, and a marked cloud is produced by 1 part in a million.

The usual standard and unknown are precipitated by running 5 c.c. of alcohol-ether solution containing 2.0 mgrms. of fat or oleic acid into 100 c.c. of water and after adding 10 c.c. of 1:4 hydrochloric acid and gently stirring or shaking and allowing to stand for 5 minutes, are read in the nephelometer.

Murlin and Riche have modified this method by pouring the fat solution into 0.05% gelatin solution which delays the coalescence of the fat globules. Woodman Gookin and Heath* have worked out a similar method for essential oils. The solvent and extracting medium for essential oils is alcohol alone, and 5 c.c. of the standard solution—containing 100 mgrms. in 100 c.c. of 95% (redistilled) alcohol—is precipitated by pouring into 25 c.c. of water, or better 25 c.c. of hydrochloric acid.

By adding acid as used in the Bloor method, I found that one could use a much weaker standard than the authors recommended and still get suitable nephelometric clouds. They were able to estimate the oils of roses, peppermint, anise, and nutmeg nephelometrically with ease and accuracy.

Proteins. Nephelometry can be very well applied to protein estimations, a solution of sulphosalicylic acid being the reagent used (Kober, J. Amer. Chem. Soc., 1913, 35, 290). A solution containing 1.0 mgrm. of protein per litre gives a marked test.

In milk the fat is first removed by adding to the diluted milk (5 c.c. of milk in about 200 c.c. of water) 10 c.c. of N/10 sodium hydroxide, making up to 250 c.c. and shaking with ether. (For further details see J. Amer. Chem. Soc., 1913, 35, 1589).

Sydney Section.

TANNING IN ACID LIQUORS, WITH COMPARATIVE TESTS.

BY F. A. COOMBS AND W. H. MCGLYNN.

These experiments were undertaken in the hope of throwing some light on the value of acid in tan liquors. The experimental process, as related to hide-sections for comparative results, has been described previously (this J., 1917, 188 seq.). It will be noted that two experiments were made with acetic and one with sulphuric acid. Each experiment includes two tests and each test consists of two pairs suitable for com-

* J. Biol. Chem., 1911, 10, 187.

† *Food*, J. Biol. Chem., 1914, 18, 263

* J. Ind. Eng. Chem., 1916, 8, 128.

parative purposes. All the tan-liquors were prepared from wattle bark and a normal and acid tannage was used for each experiment.

We have endeavoured by a series of comparative tests to show the difference between the results obtained with normal wattle liquors and similar liquors with the addition of certain amounts of acetic acid. The hide sections were prepared for the tan-liquors in the way already described (*loc. cit.*). For the acid tannage in the first two experiments, the natural acidity of the wattle liquors was found by the lime-water test and was then made up to the required concentrations by addition of acetic acid. The difference between the acidity of the liquors in the normal and acid tannages will show the amount of acetic acid used for the latter.

The influence of acid on the quality of leather during the process of tanning varies to a considerable extent according to the acid used and its concentration at various stages. Generally it may be said that tanners use acid to plump or swell the hide, thereby obtaining a stouter and consequently a more valuable leather. Our problem was one of determining its influence on the quality of heavy leather.

Our experience teaches us that all skins in the pelt state respond quickly to the plumping action of dilute solutions of various acids, but they do not respond to this action after they have been tanned. Sheep pelts are tanned in weak solutions and fix the minimum amount of tannin, but the resulting leather successfully resists the plumping action of acids. A neutral pelt is soft and flabby, differing from the acid pelt, which is firmer and stouter. The physical difference between the acid and neutral pelt will be responsible for a difference between the qualities of their respective leathers, providing they are fixed in the condition described above and that tannin is the fixing agent.

It is generally recognised that a firm and stout leather is a desirable result in the production of sole leather and therefore within certain limits the best results from a monetary standpoint will be obtained by fixing the pelt in the acid condition. A soft, pliable leather will be the result when a neutral pelt is tanned in liquors containing the

minimum amount of acid; but when a highly plumped acid pelt is placed in acid liquors capable of keeping the pelt in its swollen condition, a harsh and brittle leather is produced which, in extreme cases, will break like a biscuit. The wear by friction will always be greater on a brittle than on a pliable leather and the most prominent factor in this physical difference appears to be one of elasticity.

For the first experiment a pelt which had been delimed on the surface with lactic acid was used. This pelt was placed in the first tan liquor containing acetic acid and the tannin penetrated a certain distance into the hide, fixing a portion of the fibres and producing a normal leather. At this stage about one-fifth is tanned and the other four-fifths of the hide has fixed a certain amount of acid. As the pelt moves forward through the various tan-liquors their acidity is gradually increased and the amount of acid fixed by the untanned portion of the hide also increased until the tannin has penetrated through the hide. Under normal Australian conditions the tannin takes from three to four weeks to penetrate into the centre of the hide and therefore all the plumping must be done before the end of the fourth week. The leather tanned in the acetic acid tan liquors (first experiment) had a dark streak of brittle fibre in the centre of the hide and this brittle portion would represent that part which was not tanned after the leather had been in the tan liquors for two weeks. At this stage we apparently had an acid concentration capable of swelling the untanned portion of the hide beyond that point at which harsh leather is produced, providing it is fixed in this abnormal condition.

In dilute acid solutions the protein molecules of the hide combine with the acid to form a highly ionisable salt, and under certain conditions the concentration of diffusible ions in the hide is greater than the ionic concentration in the outer solution, which leaves the osmotic forces in the two phases in an unbalanced state and, as a result, the external solution is absorbed and the hide begins to swell. These forces are described, by

Procter and Wilson, for gelatin as an outward pull where the increase in volume is directly proportional to the pull. Now let the total elongation of the hide fibres due to any outward pull be represented by a straight line A B. If the soft flaccid neutral pelt be placed at A and the firm stout acid pelt at B, we will have a scale for the total elongation between the neutral pelt at zero and the acid pelt at the elastic limit. Suppose we now take a pelt swollen to 9° and place it in a tan liquor with the required acid concentration to keep it at that figure, then tannin would fix the pelt and give it a permanent set at 9° elongation.

When these sections were placed in tan-liquors the outer portions of the hide received a permanent set at a low figure, but as the leather was moved forward into liquors with higher acid concentrations, the figure for the permanent set would gradually increase. In this case it would appear as if the permanent set for the inner portion of the hide were too near the elastic limit for the production of good leather. Working on this theory we reduced the amount of acid during the early stages of the tanning process as shown in the second experiment, and the resulting leather was free from this fault, which was constant for all the acid leather from the first experiment.

Procter states that after the swelling has reached its definite value, it is unchanged at a constant temperature by further lapse of time, providing that no change takes place in the acid concentration of the outer solution. Thus the total elongation for a swollen pelt is directly related to this acid concentration, and if it is desirable to have a permanent set at any particular point on the scale for elongation, then the correct acid concentration must be maintained in the outer solution.

We also give results for leather swollen with sulphuric acid. The sections were treated in the usual manner before they reached the tanning process and then one-half was placed in a sulphuric acid solution for plumping purposes. It is not desirable to give a permanent set to the grain or superficial surface of the corium at a high elongation because this portion of the hide is the first to crack if the process tends to a brittle leather; therefore it is the usual custom to allow the tannin to penetrate the grain of the normal hide and then place it in the sulphuric acid solution.

Several experiments were carried out with pelt suspended in acid solutions of varied concentrations, and we finally decided to use an N/10 sulphuric acid solution for the first test in this experiment. The pelt was placed in a tan liquor 8° barkometer for 24 hours, at the end of which time the grain was permanently set. The leather then went into N/10 and N/15 sulphuric acid solution for first and second tests respectively, and was left overnight for a period of 17 hours. The remaining tanning process was the same for these sections as for the normal process. The sections were very firm when they came from the sulphuric acid solution, and the increase in weight was 1% on the lime-swollen pelt. They did not receive any lactic acid. The penetration of the tannin proceeded less quickly with the sulphuric acid than with the normal leathers and, while the acid process gave the stouter leather, or greater dimensions as represented by a straight line piercing the leather at right angles to the grain, it appeared to be the cause of a decrease in area. Thus any increase in this direction would not be directly proportional to the increase in volume.

When the partially tanned pelt was removed from the sulphuric acid solution and placed in the tan-liquors no attempt was made to keep up the acid concentration in the outer solution. The unstable collagen-sulphuric acid combination is

hydrolysed and the acid diffuses into the outer solution, where a portion displaces weak acids from those salts common to tan liquors. Under these conditions most of the sulphuric acid is removed from the leather at the end of the tanning process. Any sulphuric acid process, to be efficient, should not leave free sulphuric acid in the dry leather. This acid is used in quantities varying from 20 to 50 lb. for 50 hides, and the pelt swells to a considerable extent; but before the whole of the hide is permanently set a large portion of the acid will have been removed by the various tan liquors. With the sulphuric acid process, the amount of acid fixed by the hide reaches its maximum at the beginning of the tanning process, and if the swollen fibres are exposed to the tannin solution by cutting a piece off the hide, the cut surface appears to fix a large amount of tannin, and changes to a deep red. If, however, the conditions are such that the untanned portions of the fibre are gradually giving up acid to the outer solution before they are fixed by the tannin, the resulting leather is not a dark red colour providing sufficient acid diffuses out of the hide.

Procter and Wilson state that the rate of tanning will be a maximum for a given concentration of liquor when the potential differences are of opposite signs and the absolute value of each is a maximum. We have found that, after the second week, the acetic acid in the first experiment reached a certain concentration in the untanned portion of the pelt, and as a direct result an excess of tannin was fixed as indicated by the dark red streak in the centre of the hide. Under certain conditions the same dark red colour could be obtained with the sulphuric acid leather. To obtain these results the differences in potential must have reached its maximum for these experiments when the pelt had fixed the maximum amount of acid. As the difference in potential increases, the rate of penetration would appear to decrease, and it is probable that at a certain point, tannin is deposited on the fibre in sufficient quantities to form a barrier to further penetration.

We have seen sole leather with an untanned streak in the centre of the dark red leather and this was supposed to be due to some abnormal state in the sulphuric acid process. As the tannin diffuses into the hide it will choose the paths of least resistance and diffuse along the less dense spaces between the fibres. These spaces probably contain a weak solution of protein matter which is precipitated by the tannin, leaving what are known as air spaces in the dry leather. When the hide fibres swell under the influence of acid solutions, the outward pull may be directly proportional to the increase in the volume of the individual fibres; but in swelling they will tend to fill up any open spaces in the hide and retard the penetration of the tannin. If there are open spaces in the hide at this stage the outward pull (for a hide) would not be directly proportional to its increased volume as measured by external dimensions.

The amount of tannin fixed by a hide is proportional to the concentration of tannin in the liquors. In the normal tanning process the pelt is first placed in weak liquors. This was probably rendered necessary in the past because the hides contained a considerable amount of lime when they reached the first tan-liquors, and calcium tannate would be precipitated on the outer portion of the leather, with a tendency to retard the penetration of the tannin if strong liquors were used. The amount of tannin and calcium tannate deposited would then be at the maximum.

Strong liquors on a neutral or slightly acid pelt are supposed to give this undesirable result, which would be intensified with the higher percentages of acid as used in these experiments. There are several reasons for using weak liquors in the early stages of the tanning process, but if there is any value in the theory that an excess of tannin deposited on the fibres will retard penetration to an appreciable extent, then strong tan-liquors should not be used to fix the highly swollen sulphuric acid pelt in the early stages. A sound definition of "strong liquors" for the various stages in the process of tanning is impossible without another series of comparative tests to deal with this factor. Many tanners, more especially those who use bark and do their own leaching, would certainly start their hides in stronger liquors providing the loss was not excessive when pumping away tail-end liquors.

Our results for these experiments show that the amount of fixed tannin (see degree of tannage) increases with the acid processes, and from our water absorption tests we find that, as further amounts of tannin are fixed on the leather, greater resistance is offered to the penetration of water. The wear-resistance of leather will be proportional to the mass, other factors being equal, and as fixed tannin increases the mass this power of resistance will be proportional to the fixed tannin. If the combination between hide substance and tannin be a chemical one, then this portion of the leather is held together by cohesive forces, differing from the total solubles which are held in the leather by adhesive forces.

Both combined tannins in excess and water-solubles are capable of adversely affecting the results by imparting to the leather brittle qualities which will vary according to the tannins used. In a hot, dry climate leather containing large amounts of fixed tannins is inclined to become brittle or it loses some of its elastic properties. The same leather might give general satisfaction in Europe, where it retains that amount of water which is required to keep it in a pliable state. As far as sole leather is concerned, any brittle qualities which can be traced to any excess of combined tannins will not adversely affect the wearing qualities, providing the leather contains sufficient fatty matter and water.

The water-soluble matter in leather is brittle or plastic according to the amount of water it contains, and therefore varies with atmospheric changes, tending to a harsh, brittle leather in a dry climate and offering very little resistance to the penetration of water. Owing to its hygroscopic properties glucose is useful for keeping a leather mellow or pliable during exposure to a high temperature and low humidity, but these properties render it extremely unsuitable in any climate for sole leather which must, at certain times, resist the penetration of water to a degree not attainable with a leather containing glucose. Fatty matters make leather pliable and enable it to offer great resistance to the penetration of water. Fats, but not glucose, are the necessary constituents of a good sole leather.

Riethof* states that sole leathers for the British and United States Governments are allowed to contain 25–26% of water-soluble matter. Temperature for extraction is not given. As both these Governments are advised by experts we assume that trained leather trade chemists are satisfied that this soluble matter contributes to a considerable extent to the wear resistance properties of sole leather. Water-solubles certainly increase the mass and may contribute to this desirable result mentioned above when they contain sufficient water to make them as plastic as cobbler's wax. There is very little evidence for and a good deal against these solubles having any value as a constituent of leather.

Six duplicate tests were made in these experiments and a total of twelve pairs for comparative purposes. The total solubles are higher for the acid processes in eleven out of the twelve pairs. If the combination between hide substance and tannin be perfectly stable under conditions as laid down by the extraction process, then the total solubles must be the residue from the tan-liquors held by capillary forces in the leather when it is hung up to dry. The amount of soluble matter would depend on the volume and concentration of the solubles in that tan-liquor which is retained by the leather under conditions mentioned above. The slight difference in the thickness between the acid and normal leather would not have any great influence on the amount of soluble matter removed when the leather is washed. A glance at the tanning process will show that the concentration of the liquor remaining in the leather should be approximately constant for each pair, so that we must now prove that the volume of the liquor retained by capillary forces was greater for the acid leather, or doubt must be felt as regards the stability of the combined hide substance and tannin.

Water absorption test.

Dry leather = 100.

Sulphuric acid No. 3 ..	79.3	127	100.4	102%

The volume of the liquors will always be proportional to the interspaces of the leather. The hide sections increase in weight during the tanning process, but this increase is not equal to the amount of combined tannin and total solubles, so the difference must be due to water expelled from the leather. We find that a greater percentage of water has been expelled from the acid

* Hide and Leather.

sections, and if the interspaces in the leather have decreased to a corresponding amount we would expect to find it confirmed by the water-absorption test. The amount of water absorbed is lower for the acid sections and therefore we assume that the volume of liquor held by the leather was proportionately lower for the acid sections and consequently the total solubles should be lower. The percentage of non-tans in the total solubles is lower for the acid leather in nine out of the twelve single tests, and in this as in previous experiments we have noted the small percentage of non-tans in various leathers. Such a result may be due to the non-tans decomposing much more quickly than the tannin or it may be due to the hydrolysis of the leather.

We have shown the soluble tannins as a percentage on the total tannins in the leather and in eleven out of the twelve the results are higher for the acid tests. If it be possible to remove the combined tannin with water, then these results seem to indicate that as the fixed tannin increases, the stability of the combined hide substance and tannin decreases.

The sulphuric acid plumped leather (first test) contained 0.57% of free sulphuric acid as shown by the Procter and Searle method of analysis. This is a bad result from a practical standpoint but we could probably have removed all the free sulphuric acid with sodium acetate or calcium carbonate used in conjunction with the drum process. As the concentration of the acid is

increased in the pelt the resulting leather becomes harder and more rigid, the elasticity decreases, the amount of fixed tannin increases, and also the resistance to the penetration of water. From the commercial standpoint it is a desirable process, giving greater weight and stouter leather, but under conditions obtaining in a hot dry climate it is probable that the resistance to wear decreases.

The actual tanning process probably ceases when the fibre is permanently set, a result obtained with a liquor containing a low concentration of tannin. Any increase of tannin obtained after that point is reached can only act as a filling agent and the good results obtained from chrome sole leather show that there are better filling agents than the vegetable tannins. A considerable amount of leather is struck through in the pits and then placed in the drum to be filled up with extract, etc. The weak point in this process is the filling agent. The tanner's process is a correct one but the material with which he is supplied is not good. What is wanted is a substance insoluble in water and one that will remain plastic when the leather is dry.

Our work confirms some of the previous results obtained by J. R. Blockey.

Yorkshire Section.

Meeting held at Leeds on Friday, February 4th, 1918.

PROF. J. W. COBB IN THE CHAIR.

LOSS OF INDICAN DURING AIR-DRYING OF INDIGO LEAF.

BY PROF. E. R. WATSON, M.A., D.Sc.

This investigation was undertaken in connection with an examination of the chemical nature of the substances in solution in seeth-water (A. G. Perkin, Chem. Soc. Trans., 1916, 109, 210 *et seq.*).

The percentage of indican in the samples of leaf examined was determined by boiling the aqueous extract with isatin and hydrochloric acid and weighing the indirubin produced, according to the method worked out by Gaunt, Thomas, and Bloxam, under Prof. A. G. Perkin's directions (this Journal, 1907, 1178).

The method of extraction described by Orchard-

son, Wood, and Bloxam (this J., 1907, 7) did not prove efficient for fresh leaf, probably because the unbroken epidermis of the fresh leaf is more or less impermeable to water. It was found that all the indican was extracted if boiling water was poured over the leaves and the water then boiled with the leaves for one minute. Nothing less than this was sufficient, as the following figures show:—

Indirubin from 10 grms. of fresh leaf.

	Sample 1.	Sample 3.	Sample 4.
Extraction according to method of Orchardson, Wood, and Bloxam (<i>loc. cit.</i>)	0.0190	—	—
Leaves steeped in boiling water for 1 minute	—	0.0877 } 0.0817 }	0.0843
Boiling water poured over leaves and water boiled with leaves for $\frac{1}{2}$ minute	—	—	0.0945
Idito, boiling for 1 minute ..	0.1008	0.1057	0.0970

The method of extraction adopted was as follows:—Ten grms. of leaf was placed in an Erlenmeyer flask of 250 c.c. capacity and about 75 c.c. of boiling water poured over them. The water in the flask was at once brought to the boil and kept at the boil for one minute. The water was quickly drained from the leaves and filtered and the leaves were treated with successive quantities of water at 60° C., each quantity being allowed to stand with the leaves for one minute, then drained off, filtered, and added to the extract until its volume was made up to 250 c.c. This extract was treated with the same quantity of isatin and hydrochloric acid as prescribed by Gaunt, Thomas, and Bloxam (*loc. cit.*) for 5 grms. of dried leaf. (It was found that fresh leaf lost about two-thirds of its weight on air-drying.) For the sake of uniformity all samples of leaf, both fresh and air-dried, were extracted in this way.

The first sample of leaf (kindly supplied by Mr. R. S. Finlow, Bengal Agricultural Department) was collected in Behar, packed very loosely in a glass-stoppered bottle, and sent by post to Dacca for analysis, so that analysis was made two days after the leaves were collected. The second, third, and fourth samples were plucked at different times from plants grown in Dacca and the fresh leaf was analysed within an hour of plucking. For air-drying the leaflets (separated from the stalks—all analyses were for the separated leaflets) were spread in a thin layer on sheets of filter-paper, covered by a fine cotton net, and allowed to stand in a N. verandah until they were practically constant in weight. This took 3–4 days. The results obtained are tabulated below.

Indirubin obtained from 10 grms. of leaf (weighed in fresh condition).

	Leaf extracted whilst fresh.	Leaf extracted after air-drying.
Sample 1 ..	0.1008	0.0568 } 0.0515 }
Sample 2 ..	0.0825 } 0.0832 }	0.0610 } 0.0593 }
Sample 3 ..	0.1057	0.0763 } 0.0732 }

In each case air-drying has caused a very considerable loss of indican. Samples 2 and 3 lost 27.5 and 29.3% of indican respectively. Sample 1 lost much more. This was the sample which had stood for 2 days in a glass-stoppered bottle before examination.

If leaf is packed closely and allowed to stand, some fermentation takes place and all the indican may disappear. In this case a good deal of indigo-blue is deposited in the leaves. From

this it was expected that protracted drying in thicker layers would cause a greater loss of indican; and this was found to be the case.

	Leaf extracted whilst fresh.	Extracted after air-drying in 3–4 days.	Extracted after protracted air-drying in thicker layers.
Sample 3..	0.1057	0.0763 } 0.0732 }	0.0597

It was also found that rapid drying in a steam-oven completely destroyed the indican.

The results obtained are of some general interest as they indicate that any drying or standing of the leaf before extraction will considerably reduce the yield of indigo. In earlier days the leaf was sometimes dried before extraction; e.g., in Crookes' "Dyeing and Calico Printing," 1874 edition, pp. 448 and 451, there is a quotation (Twist) to the effect that in Guzerat the leaves were dried in the sun; and in Bancroft's "Philosophy of Permanent Colours," Vol. 1, p. 173, it is stated that in some cases the stems and leaves are put into the steeping-vat at once, in others after being more or less dried. It has been stated that in the Madras Presidency it was the custom to dry the leaves before steeping, but apparently it is not the practice there to-day. Gaunt, Thomas, and Bloxam (*loc. cit.*, pp. 1180–1181) remark that probably there is considerable loss of indican during air-drying, but so far as the writer is aware the present note is the first record of any reliable investigation of the point. The loss of indigo-yielding glucoside which may occur if the leaf is not put into the steeping-vats immediately is evidently very considerable, and obviously arrangements should be made to avoid any delay. In the cane-sugar industry it has long been recognised that commercial success depends on getting the cane into the factory without delay, as otherwise some inversion of the cane-sugar occurs. Apparently delay is equally serious to the indigo-planter, yet the present note records the first quantitative investigation as to whether there is any loss if the leaf is allowed to stand or dry before putting into the steeping-vat.

SEPARATION OF SECONDARY ARYLAMINES FROM PRIMARY AMINES.

BY TUDOR WILLIAMS PRICE, B.A., M.Sc., A.I.C.

When secondary arylamines are prepared in the usual way by heating a primary amine with an alcohol in the presence of a condensing agent such as sulphuric acid or hydrochloric acid, the product obtained is always contaminated with unchanged primary amine and also with tertiary amine. The isolation of the secondary amine by fractional distillation of the crude product is tedious and also unsatisfactory owing to the closeness of the boiling points of the primary, secondary, and tertiary amines. The isolation of the secondary amine by conversion into the nitrosamine and reduction of the latter is expensive and more-over produces low yields, so is inapplicable except on a purely laboratory scale.

During the course of an investigation into the conditions affecting the production of ethyl-toluidine, it was found that a very satisfactory and economical separation of the secondary amine from *o*-toluidine could be made by means of

sulphuric acid. After the method had been worked out, it was discovered that a similar method had been used by Gnehm and Blumer (this J., 1899, 18, 129) in the separation of methyl-*o*-toluidine from *o*-toluidine. Few details are given by these authors and consequently it was thought that it would be of interest and utility to publish the details worked out by the present author.

Primary aromatic amines combine with concentrated sulphuric acid to form solid sulphates which are insoluble in the free base. Secondary and tertiary amines, on the other hand, under the same conditions form syrupy sulphates which dissolve in the free base. It is found that an economical method of separation of these substances can be based on this difference in behaviour.

If a mixture of primary, secondary, and tertiary amines is treated with the requisite quantity of 96% sulphuric acid to combine with the primary amine present, the distribution of the sulphuric acid is influenced by two factors, namely, the relative strengths of the bases present and the degree of insolubility of their sulphates. Experiments have shown that the latter factor predominates and that practically the whole of the primary amine is precipitated as sulphate. A small proportion only of the sulphuric acid combines with the alkylated amines but the sulphates of these compounds remain dissolved in the excess of the amines, and consequently the primary sulphate can be removed by filtration.

Experimental. The sulphuric acid used was of sp. gr. 1.84 (168° Tw.). The ethyl-*o*-toluidine was made by heating *o*-toluidine and ethyl alcohol with sulphuric acid in an autoclave. The crude product was once distilled to remove alcohol and impurities of high boiling point.

The amount of *o*-toluidine present in ethyl-*o*-toluidine was determined by means of the dye formed with R-salt (sodium- β -naphthol-3.6-disulphonate), observing the precautions recommended by Reverdin and de la Harpe (Ber., 1889, 22, 1004).

*Separation of ethyl-*o*-toluidine from *o*-toluidine.* The crude ethyl-*o*-toluidine generally contains 10–15% of unchanged *o*-toluidine and the amine used in the majority of these experiments contained this percentage of *o*-toluidine.

A preliminary experiment, using the theoretical amount of sulphuric acid required to combine with all the *o*-toluidine, showed that the amount of primary base was reduced from 10% to 7%.

A series of experiments was then carried out, in which the proportion of sulphuric acid to the mixed bases was gradually increased until it was greatly in excess of the amount required to combine with all the *o*-toluidine present. Great heat is developed during the combination, and after cooling to ordinary temperature the mixture was filtered. Filtration was tedious and the sulphate could not be obtained free from base. Washing with ether removed the adhering base from the sulphate. The results are shown in Table I.

These results show that even with a 30% excess of sulphuric acid a complete separation was not obtained, and that an excess of about 15% was necessary to reduce the primary base content from 10% to 1–2%. Later, working with much larger quantities it was found that only a very slight excess of sulphuric acid was required and that an excess larger than about 3–5% produced some syrupy sulphate of the secondary amine, which made filtration almost impossible.

Freezing out of sulphate. The first series of experiments showed that a complete separation of the primary and secondary amines is not obtained even when an amount of sulphuric acid greatly in excess of that required to combine with all the primary amine is added. This might be due to the slight solubility of the *o*-toluidine sulphate in the secondary amine at room temperature. Accordingly 150 grms. of ethyl-*o*-toluidine containing 10% *o*-toluidine was treated with 8 grms. of 96% sulphuric acid; in one case the mixture was cooled to room temperature and in the other to –13° C. by means of a freezing mixture. The sulphate was filtered in each case and the amount of primary amine left in the mixture determined. In the first case, 102 grms. of filtrate was obtained containing 1.6% of *o*-toluidine; the sulphate yielded 39 grms. of amine containing 24.8% of *o*-toluidine. When the mixture was cooled to –13° C. and filtered, the filtrate weighed 103 grms. and contained 1.8% of *o*-toluidine; the sulphate yielded 39 grms. of amine containing 22.3% of *o*-toluidine.

These experiments show that there is no difference in the separation when the mixture is cooled to –13° C. or to room temperature and that the incompleteness of the separation is not due to a slight solubility of the *o*-toluidine sulphate in ethyl-*o*-toluidine.

The probable explanation of the incompleteness of the separation is that although the bulk of the sulphuric acid combines with the *o*-toluidine, owing to the insolubility of its sulphate, yet a certain amount combines with the ethyl-*o*-toluidine. If this be true, then successive treatments with sulphuric acid should diminish the amount of *o*-toluidine left in the mixture until it becomes a negligible quantity. To confirm this view some ethyl-*o*-toluidine containing a high percentage of *o*-toluidine was treated as described below.

100 grms. of ethyl-*o*-toluidine containing 16% of *o*-toluidine was treated with 8 grms. of 96% sulphuric acid. After filtration 50 grms. of ethyl-*o*-toluidine containing 6.9% of *o*-toluidine was obtained. The 50 grms. of ethyl-*o*-toluidine was treated with 2 grms. of 96% sulphuric acid and filtered. The filtrate weighed 36 grms. and contained 1.3% of *o*-toluidine.

In another experiment 2800 grms. of ethyl-*o*-toluidine containing 12% of primary base was treated with 180 grms. of 96% sulphuric acid and put through a filter press after cooling to room temperature. 1850 grms. of ethyl-*o*-toluidine containing 2.9% of primary base was obtained.

TABLE I.

Effect of excess of sulphuric acid upon the separation of ethyl-*o*-toluidine from a mixture containing 10% *o*-toluidine.

No. of Expt.	Mixed bases, wt. in grms.	Sulphuric acid.		Filtrate.		Base obtained from sulphate.	
		Wt. in grms.	Excess.	Wt. in grms.	Primary base.	Wt. in grms.	Primary base.
1.....	100	5.0	9	71	3.3	22	26.4
2.....	150	8.0	14	102	1.6	39	24.8
3.....	100	6.0	30	69	1.4	13*	49.6

* Sulphate washed with ether before neutralising.

1800 grms. of the filtrate from the last experiment was treated with 30 grms. of 96% sulphuric acid and filtered. 1625 grms. of ethyl-*o*-toluidine containing 0.6% of *o*-toluidine was obtained. These experiments confirm the statement that successive treatments with sulphuric acid are necessary owing to its distribution between the two amines.

Large scale experiments. The separation of ethyl-*o*-toluidine from *o*-toluidine having been successfully performed on a laboratory scale, it was decided to apply it on a semi-manufacturing scale. For this purpose filtration of the sulphate is too slow and a centrifuge was used. In order not to clog the centrifuge by the syrupy sulphate of the secondary base, the amount of sulphuric acid used was exactly sufficient to combine with all the *o*-toluidine present. 187.5 lb. of ethyl-*o*-toluidine containing 15.6% of *o*-toluidine was treated with 14 lb. of sulphuric acid. After standing overnight it was filtered and 114 lb. of ethyl-*o*-toluidine containing 2.7% of *o*-toluidine was obtained. This contained 70% of the secondary amine originally present. In a second experiment, 184.5 lb. of ethyl-*o*-toluidine containing 4.1% of primary amine was treated with 3 lb. 11 oz. of sulphuric acid. After passing through the centrifuge 152.5 lb. of ethyl-*o*-toluidine containing 1% of primary amine was obtained. This is a yield of 85% of the secondary amine originally present.

These results show that the method can be applied to large scale working equally with laboratory experiments. The yield of secondary amine after purification is always better the lower the original content of primary base. This is due to the secondary base being retained by the sulphate of the primary base on the filter or centrifuge. To obtain a greater yield the sulphate can be washed with an anhydrous solvent, such as benzene or alcohol, in which the sulphate is not appreciably soluble. By distillation the solvent and secondary amine can be recovered separately. This was done with the sulphate from the last two experiments. The combined sulphates as taken from the centrifuge weighed 96 lb. The theoretical weight should be 56.5 lb. calculated on the sulphuric acid used. Hence 39.5 lb. of secondary amine was retained by the sulphate. The sulphate was accordingly churned up with 100 lb. of benzene in a closed vessel and then centrifuged. The benzene was distilled and the residue above 100° C. weighed 40.5 lb. and contained 2.0% of *o*-toluidine. The sulphate was air-dried for several days and weighed 55 lb. The above figures show that an almost theoretical yield of ethyl-*o*-toluidine can be obtained when the sulphate is washed free of adhering secondary amine by an anhydrous solvent.

For a continuous process the best solvent is absolute alcohol, since then the sulphate need not be dried but can be utilised at once for a fresh autoclave charge, after analysis. This was done and the resulting crude ethyl-*o*-toluidine was of the same quality as when obtained from *o*-toluidine, alcohol, and sulphuric acid.

The method outlined above is therefore an economical and satisfactory method of separating ethyl-*o*-toluidine, since the *o*-toluidine sulphate,

and the alcohol used in washing it, can be used for a fresh autoclave charge and no non-essential material is used at all.

The above method of removing a primary amine is applicable to other primary amines as is shown by the following experiments.

Separation of mono-methylaniline from aniline. 100 grms. of monomethylaniline containing 10% of aniline was treated with 5 grms. of 96% sulphuric acid and filtered. 80 grms. of monomethylaniline containing 1.8% aniline was obtained. The yield is 87% of the monomethylaniline originally present.

Separation of dimethylaniline from aniline. 100 grms. of dimethylaniline containing 12% aniline was treated with 6 grms. of 96% sulphuric acid and filtered; the yield was 75 grms. of dimethylaniline containing 0.4% of aniline. This is equivalent to 83% of the dimethylaniline originally present.

Separation of a mixture of mono- and di-methylaniline from aniline. 100 grms. of a mixture of mono- and dimethylaniline containing 5% of aniline was treated with 2.5 grms. of 96% sulphuric acid and filtered; yield = 84 grms. of mixed amines containing 0.1% of aniline. This is equivalent to a yield of 88% of the mono- and dimethylaniline originally present.

Separation of ethylaniline from aniline. 50 grms. of ethylaniline containing 11.3% of aniline was treated with 2.8 grms. of sulphuric acid and filtered. 36 grms. of ethylaniline containing 0.42% of aniline was recovered. This is equivalent to a yield of 80.6% of the secondary amine originally present.

Separation of diethylaniline from aniline. 50 grms. of diethylaniline containing 7.8% of aniline was treated with 2 grms. of sulphuric acid and filtered. 38 grms. of diethylaniline, containing 0.15% of aniline was recovered. The yield is therefore 82.3% of the tertiary amine originally present.

The above results show that the sulphate method of removing a primary amine is applicable to a mixture of primary and secondary or primary and tertiary, or primary, secondary, and tertiary amines.

SUMMARY.

Experiments have been carried out on the separation of primary arylamines from secondary and tertiary amines by means of sulphuric acid. The mixture is treated with a quantity of sulphuric acid sufficient to combine with all the primary amine and filtered. If desired a second treatment may be given.

An increased yield can be obtained by washing the sulphate of the primary amine free from secondary or tertiary amine by means of an anhydrous solvent. If desired, the sulphate can be used for a fresh autoclave charge.

In conclusion, the author wishes to express his thanks to Messrs. Nobel's Explosives Co., Ltd., and to Mr. Wm. Rintoul, Manager of the Research Section, for the facilities offered for carrying out this work and permission to publish the results.

A CONVENIENT ARRANGEMENT FOR ILLUMINATING A CHEMICAL BALANCE.

BY B. D. PORRITT, M.Sc.(LOND.), F.I.C.

In arranging the illumination of a balance, in addition to securing satisfactory lighting of the graduated beam, pans, and pointer, care must be taken to avoid any unequal expansion of the balance arms due to heat, or disturbance of equilibrium arising from air currents. For these reasons the source of light should be placed symmetrically to the beam at the top of the balance case and should be as extensive as possible in order to reduce heat radiation to a minimum and to distribute uniformly such as is unavoidable.

The type of electric lamp in which the light source consists of a metallic filament suspended along a narrow tube seemed to be free from the defects of the ordinary type, since the heat evolved would be slight and largely dissipated, and further, owing to the shape of the lamp, it could be easily arranged so that any slight heating effect should be uniformly distributed over the beam of the balance.

In the arrangement here described a "tubolite" metallic filament lamp of 16 candle-power, 8½ inches long, is employed, enclosed in a semi-circular aluminium reflector which serves both to direct the light through the glass top into the balance case and to screen the light source from the view of the person weighing. Both these fittings are standard articles in the electrical trade.

In order to ensure the lamp and reflector always being placed symmetrically to and slightly in front of the balance arm, two upright brass springs are attached to the wood work of the balance case and into circular counter-sunk holes in these are sprung the bosses at each end of the reflector.

The lamp and fittings can therefore be removed for cleaning or other reasons by merely loosening the springs, and, to facilitate this operation and to protect the latter from injury, they are each screened by a standard of polished ebonite or hard wood. By this device the balance and its source of illumination are self-contained, and the case may be altered in position at will by merely lengthening the flexible lead or by making connection to another point of the electrical supply.

Experiments indicate that the increase of temperature inside the balance case under normal conditions of weighing by such artificial illumination should not amount to more than 2°–3° C. Such a variation, when uniform, should not affect the accuracy of an ordinary analytical balance giving trustworthy results over the range of temperature variation experienced in ordinary laboratory practice.

Evidence has also been adduced that no disturbance of equilibrium due to uneven heating of the balance arms or air currents need be feared when employing this form of illumination.

In conclusion, I have to express my indebtedness to Mr. A. C. D. Smith and Mr. D. McKinnon, of the Engineering and Vulcanite Departments respectively, for their co-operation in designing and making the device which forms the subject of the present communication.

DETERMINATION OF NITROGEN CONTENT OF RUBBER.

BY MATTHEW HOWIE.

Some time ago it was necessary to determine the nitrogen content of a very considerable number of samples of plantation rubber. The nature of the nitrogen compounds present in rubber is still uncertain, but it was thought that they would be fairly easily decomposed into ammonia, and this conjecture proved later to be correct. The method adopted was Wilfarth's copper sulphate modification of the Kjeldahl process, which gave complete satisfaction.

It is very generally held that in Kjeldahl estimations, of whatever kind, the end point or the point at which digestion with sulphuric acid may cease is when the solution becomes clear. The factor which should decide the completion of any determination, however, is not the point at which the solution becomes transparent but that at which the nitrogen compounds present have been completely converted into ammonia. Owing to the large proportion of hydrocarbons present in rubber, it was found that in practically every case at least 6 hours was necessary to clarify the solution, and it was decided to carry out an investigation with a view to determining whether or not the time of heating could be curtailed.

In each determination about 1 grm. of rubber was digested with 30 c.c. of sulphuric acid, 7 grms. of potassium sulphate, and about 1 grm. of anhydrous copper sulphate. Six separate estimations were carried out in which after 1, 2, 3, 4, 5, and 6 hours respectively, the heating was discontinued and the nitrogen figure determined in the usual way. The mixture digested for 6 hours had become quite transparent although not colourless; the others still contained varying proportions of suspended carbon. The results obtained are given in the following table.

Time of heating. Hours.	Plantation sheet.		Manihot rubber.
	Sample I. Nitrogen %.	Sample II. Nitrogen %.	Nitrogen %.
1	0.19	0.31	0.68
2	0.20	0.30	0.70
3	0.23	0.32	0.72
4	0.24	0.33	0.72
5	0.23	0.32	0.73
6	0.24	0.32	0.72

These results show that, for rubber at any rate, it is not necessary to clear the solution, and that from 3–4 hours is quite long enough to get the maximum nitrogen figure.

CORROSION OF LEAD ROOFING.

(See this J., 1918, 39 T.)

DISCUSSION.

MR. F. SOUTHERDEN writes as follows:—In May last I examined two samples of a yellowish-white incrustation formed by the corrosion of lead roofing at Axminster Church. The material, like that analysed by Prof. Brame, had the characters of commercial white lead, though of poor colour.

On ignition, the loss of weight was 13.6% and 13.2% respectively on the two samples, as compared with 13.7% required by the formula, $2\text{PbCO}_3, \text{Pb}(\text{OH})_2$. The lead had been laid on oak boards, and both the oak and lead of the south aisle, from which the samples were taken, had been renewed as recently as 1909. On turning up the sheets in several places the oak boarding was found to be very thickly coated with the deposit, 3.6 oz. (exclusive of flakes left on the lead sheet) being taken from an area of 6 in. by 6 in.; that is, nearly 7 lb. of lead per sq. yd. had been destroyed in a period of 8 years. Perforation of the lead was observed at three points. It is worthy of special note that the lead of the nave roof, laid upon deal in 1833, is in quite good condition. The danger of laying lead upon oak is, I understand, generally appreciated by architects, being attributed to the tannin present in the wood, and experiment shows that a solution of ordinary tannin exerts a solvent action on clean lead. For the dates given I am indebted to Mr. Harbottle Reed, F.R.I.B.A., the architect consulted, who also took the samples.

Meeting held at Burlington House on Monday, March 4th, 1918.

DR. C. A. KEANE IN THE CHAIR.

SOME REACTIONS OF ACETYLENE.

BY W. R. HODGKINSON, C.B.E.

It is well known that acetylene polymerises, mainly to benzene, when heated in a closed or partially closed vessel at 120° – 150° C. At higher temperatures and pressure above normal, and especially at varying pressures, acetylene decomposes into carbon and hydrogen.

The gas can, however, be passed, at a moderate speed, through a glass or silica tube heated to 600° – 800° C. either alone or diluted with an inert gas as nitrogen or hydrogen chloride or coal gas, for a moderate time (20–60 minutes) before any serious deposition of carbon occurs. The nature of the glass has a decided influence on the rate of decomposition. Silica has less effect than soda-glass.

1 hour. 1050° C.

I.

Various metals were heated to temperatures from 100° to 1060° C.* in a stream of acetylene for like time periods. Cadmium, zinc, lead, tin, copper, aluminium, and others showed no particular action at temperatures up to their melting points. No change was found in the physical state of the metals, and no carbon was taken up by them, and the carbon deposited burnt off without residue.

Iron, nickel, cobalt, and to a lesser extent manganese, tungsten, platinum, and palladium, almost in this order, showed a decided reactivity when heated, in some cases to very moderate temperatures (*e.g.*, 200° C.), in acetylene, either pure or diluted.

Under favourable conditions of temperature and supply of the gas, the metal, if in moderately small pieces as wire, frequently glowed, the glow passing along the whole mass of metal employed. Carbon deposited on the metal and, after attaining a moderate thickness, the layer peeled off and another formed.

In the case of iron the strength of the metal was retained—in fact somewhat increased; in the case of nickel and cobalt (and to a lesser extent some

2 hours. 1050° C.

II.

of the metals before mentioned) a great physical change was observed. They became quite brittle, breaking up on attempting to bend them, and also showed very decided corrosion and pitting. This action (with nickel) commenced at comparatively low temperatures, *e.g.*, 200° C., and became rapid at 600° C.

In the case of iron, a more or less deep carburisation resulted. With nickel and cobalt carburisation was also observed.

The most remarkable part of this action of acetylene is that as the carbon of the acetylene enters the metals (Fe, Ni, Co), some metal enters into and is contained in the soot-like deposit around the metal. This extrusion or volatilisation of the metal was found to occur to a maximum extent with nickel, followed in order by cobalt and iron. A nickel wire (No. 14) was in fact entirely dispersed or disseminated into the sooty

* Temperatures were controlled by melting points of metals or by Rh-Pt pyrometer.

deposit by heating for a few hours in the gas stream.

The amount of metal contained in this black deposit was found to vary considerably in different experiments. The cause of variation is not yet quite determined.

In some cases as much as 15% of nickel was obtained, in others about 5%. With iron 3% and more has been observed. Dilution of the acetylene was found not to stop the wandering of the metal, but simply to reduce the rate a little.

The carburising of iron by heating in acetylene is very rapid, especially at temperatures above 800° C., and many observations indicate that it reaches a maximum just below 1000° C. The type of carburisation is quite peculiar, the carbon showing distinct diffusion into the metal. The accompanying photomicrographs are of iron carburised by heating in acetylene for different periods at 1050° C.

Ammonia was used to dilute acetylene in some experiments on metals because it prevented to a remarkable degree the deposition of carbon from acetylene by heat, and also because the flame of the mixture was nearly smokeless.

In this gas mixture, iron, nickel, and cobalt were found to be more rapidly carburised than by acetylene alone, and the amount of extraneous carbon, or soot, reduced.

It was imagined that the cause of the more rapid absorption of carbon by the metals might be due to the simultaneous formation of a nitride and possibly its further reaction with the acetylene.

Iron (or other metal) was heated in ammonia to 800° C. At something below this temperature fine iron wire was quickly converted into nitride, Fe_3N .

Ferrous nitride heated in acetylene lost its nitrogen and the iron became highly carburised.

3 hours. 1050° C.

III.

Unfortunately, the physical change on conversion into nitride was not altered by the subsequent heating with acetylene. The iron remained brittle. On heating to bright redness and quenching, the steely structure of a highly carburised iron was obtained.

Further experiments showed that when ferrous nitride was heated in acetylene, ammonia was formed, but the matter was not followed up quantitatively.

Amines, as aniline, etc., have been found to act as very rapid carburising agents on iron and nickel.

Many benzenic compounds (benzene, toluene, phenol, aniline, naphthalene, and others), when passed as vapour over nickel or iron, were found to act in a manner somewhat similar to acetylene—that is, a deposition of soot formed on the metal and a quantity of the metal was found to have wandered into this soot. In some cases the amount of nickel in the “soot” (benzene, aniline, phenol) was greater for the same time and temperature of heating than with acetylene.

Iron and other metals were observed to act in a similar manner, but not to the same degree as nickel.

DISCUSSION.

Mr. WALTER REID remarked that iron burners would not work with acetylene even when they were chilled; apparently from the experiments made by Dr. Hodgkinson the destruction of the iron was due to volatilisation. The experiments also appeared to explain why acetylene black always contained iron.

Mr. GARDNER asked if the author had considered the possibility of carbon monoxide being present in the acetylene in the case of nickel. A very small quantity would cause vaporisation.

Dr. M. O. FORSTER believed that the gas given off from the tube would be found to contain cyanogen; it might be possible to produce aniline.

Dr. R. LESSING mentioned that iron was invariably found in coal tar and pitch. In most cases this was locked up in the free carbon. The ash in retort carbon also contained iron, but this was partly due to mechanical admixture of coke dust containing iron in the ash. The carbon or soot deposited during thermal decomposition of hydrocarbons, e.g. coal gas, always contained minute traces of iron, which could not be due to mechanical impurities. Whether this decomposition of iron was due to reactions of acetylene or of some hydrocarbons which were present in coal gas in much larger proportion than acetylene was difficult to say.

Prof. HODGKINSON replied that there was no carbon monoxide present as there had been no oxygen in the tube. It was possible that there were carbides of iron and nickel which vaporised slightly and then decomposed into metal and carbon. Cyanogen was present in the gases from the tube.

ACID-RESISTING IRON AND ITS USES IN CHEMICAL PLANT.

BY S. J. TUNGAY.

For many years chemists and metallurgists sought some form of metal which could be adapted to the requirements of the chemical industry, for the purpose of resisting the corrosive action of acids, but it is only in comparatively recent years that great developments have taken place in the introduction of forms of acid-resisting iron, which are suitable for the manufacture of chemical plant.

It was long recognised that the replacement of brittle, friable, or uncertain materials, ordinarily used for the construction of chemical plant, such as glass, earthenware, porcelain, pottery, or the more recently developed forms of fused quartz or silica, by a metal of the nature of cast iron, would present great attraction alike to the chemist, the chemical engineer, and the chemical manufacturer, provided that such metal could be made to resist acids. Many of the difficulties against which the chemical engineer has long had to contend were occasioned by the limitations in the character of materials that could be used for the construction of plant, owing to the highly corrosive nature of the various reagents and chemical substances for which the plant was to be used. Once a metal of reasonable strength and of reasonably certain behaviour for dealing with acids could be

obtained, a large number of objections and difficulties in the way of construction of plant were easily overcome. The obvious utility, therefore, of a suitable metal in the form of iron which would withstand the corrosive action of sulphuric acid or nitric acid, or a mixture of the two, was of such profound interest to the chemical industry as to open up a fertile field for research, particularly in view of the vast possibilities of such a product on a commercial scale.

Various iron alloys have been known for many years which are more or less resistant to the corrosive action of such acids as sulphuric, nitric, and hydrochloric acids, and long since it has been proved in the laboratory that a pure form of iron could be rendered resistant to either sulphuric or nitric acid by the addition of a suitable proportion of silicon, chromium, or other elements. The development and application of such metals upon a commercial or industrial basis was not, however, approached until some twenty years ago. In Paris, Jonvre was successfully making castings of small beakers, pans, and evaporating dishes in a form of passive iron which consisted largely of a refined cast iron with a high silicon content, but he was compelled to confine his operations chiefly to small castings and small vessels. Later, in Germany, "Neutrалеisen," so-called, was produced by more than one metallurgical house for the purpose of making castings to withstand nitric or sulphuric acid, but its use was both transitory and fraught with much discouragement, to the end that one industrial concern decided to abandon its manufacture, whilst another found itself surrounded with continued difficulties and disaster except as far as concerned the manufacture of small castings.

The composition of acid-resisting iron has been in some quarters guarded with much jealousy and surrounded with secrecy, notwithstanding the fact that to the competent chemist or metallurgist the secret of its composition could not long be maintained. There is perhaps something to be said after all in favour of guarding a metal alloy as a secret compound, in view of the fact that under the present condition of the British patent law it has been found that a patent covering a metal alloy comprising two or more known metals, cannot be held as valid.

In more recent years the development of the electric furnace has proved to be a valuable aid to the satisfactory commercial production of such alloys as ferro-silicon and ferro-chromium, and consequently these and other ferro-alloys are now produced both of good quality and in good quantities in many countries, chiefly perhaps in Norway, Sweden, Italy, Russia, and very extensively in America.

In America, Kowalke has made considerable research to determine the resistance to corrosion of alloys of iron and silicon, and I am able to quote some very remarkable figures as follows:—

Loss in 10% sulphuric acid.

Si %.	Area, sq. cm.	Cumulative loss, %.		
		51 hrs.	75 hrs.	141 hrs.
2.5	15.7	1.6	4.1	6.5
3.3	21.9	64.9	87.5	92.8
7.4	11.5	31.0	48.9	62.0

Certain figures in these tests are worthy of special remark. It is particularly noteworthy that silicon present in a lesser quantity than 12% does not promote a satisfactory resistance to corrosion, whilst when the silicon content reaches 19% or upwards the acid-resisting quality of the alloy again falls. Once, however, the character of these alloys was determined, the satisfactory production of them upon a commercial scale was found by the earlier undertakings to be a somewhat speculative industry, as it easily occurs, except with most careful working of the furnaces, that much of the silicon which should enter the alloy, is lost in the form of "graphite," and the alloy produced is ultimately found to be so deficient in silicon as to be no more resistant to corrosion than ordinary cast iron.

In addition to the serious difficulties presented by the considerable shrinkage of these non-corrosive iron castings during cooling, which amounts to slightly over $\frac{1}{4}$ -inch per foot in each direction as compared with a shrinkage of about $\frac{3}{32}$ -in. per foot in the case of ordinary cast iron, the presence of graphite in any considerable quantity causes disaster. The carbon and phosphorus content of the iron must also be low, otherwise during the process of cooling these compounds may tend to separate out and form entectics, the separated compounds resulting in pellets which are found in small blow-holes or cavities in the thickness of the metal, and this notwithstanding that the alloy may have been carefully and correctly mixed in the first instance.

Some tests recently made at the Manchester School of Technology show these eutectics to consist largely of phosphorus and silicon. Whilst a normal average quality of pig iron may show an analysis of say, Si 3.45, S 0.03, P 0.64, Mn 0.66, combined carbon 0.27, graphite 3.48, Fe 91.47%, to produce an acid-resisting or non-corrosive iron it is necessary to get rid of what may be termed the 10% of "impurities" and make the alloy from as pure a form of high grade iron as possible.

These difficulties have largely been overcome by suitable furnaces and by improved manipulation in mixing the metal, with the result that in present commercial practice it is found quite possible to produce a satisfactory acid-resisting iron; but its application for the manufacture of vessels and plant of large capacity suitable for the requirements of the chemical industry, had up to recent years on all sides resulted in failure and disappointment, and often much loss.

It is due to the energies of British chemical engineers and metallurgists that great manufacturing difficulties have been surmounted, and that we are now enabled to produce a large variety of vessels and plant suitable for the manufacture of nitric and sulphuric acids, and suitable for chemical processes involving the use of such acids for the advancement of chemical progress and industry. Lasting credit is due to men like Jouve, Lennox, Pearce, and Marsden of Manchester, who each sought to overcome the manufacturing difficulties of making large castings for construction of plant from these different alloys. This has been followed by more recent work by Dr. Rossi in Italy, and others in the United States.

Whilst, as I have already stated, there may be no secret as regards the composition of the alloy, its satisfactory manipulation for producing reliable vessels and castings is a question of craftsmanship of the highest order. These methods of manipulation vary at the different works producing acid-resisting iron castings, and are for the most part somewhat jealously guarded.

I exhibited some specimens of acid-resisting iron castings at the Chemical Engineering Exhibition in London in 1913, which provoked much favourable comment, notably some parts of nitric acid condensation plant and vessels for the concentration of sulphuric acid. As a result, chemical manufacturers rapidly displayed an interest in plant constructed of "Ironac" acid-resisting iron.

Following are the results of some corrosion tests made in the course of practical work, with test pieces from large vessels made of "Ironac" acid-resisting iron, being chiefly test pieces from works plant of large capacity.

Corrosion tests on "Ironac" acid-resisting iron.

Acid.	Initial weight, grams.	Loss after boiling at 150° C. for :		
		24 hrs.	48 hrs.	72 hrs.
Sulphuric acid 65%	112.648	Nil.	Nil.	Nil.
Sulphuric acid 20%	115.207	Nil.	Nil.	Nil.
Nitric acid 90%	13.392	0.011	0.038	0.074
Nitric acid 30%	116.629	0.013	0.016	0.016

Loss after boiling in mixed acids as follows :—

Mixed acid.	—	Original weight, grms.	Loss in grms.
65% H ₂ SO ₄ 2% HNO ₃ 33% water	24 hrs. at 150° C.	(1) 303.0	Nil
		(2) 385.59	Nil
		(3) 15.903	Nil
	15 hrs. at 150° C.	(1) 302.9	0.1
		(2) 385.53	Nil
		(3) 15.903	Nil
	15.5 hrs. at 150° C.	(1) 302.6	0.3
		(2) 385.5	0.09
		(3) 15.903	0.08
	12.5 at 150° C. to 260° C.	(1) 302.6	Nil
		(2) 385.5	Nil
		(3) 15.903	0.08

After each experiment the specimens were boiled out with water several times and then dried on the hot plate at a temperature of about 400° C.

The above tests are of more value to the chemical engineer or works chemist, inasmuch as they do not relate to special test pieces prepared for the laboratory.

One authority has given the following physical constants of acid-resisting iron as compared with cast iron :—

	Ordinary cast iron.	Acid-resisting iron.
Density	7.3	6.8
Tensile strength (tons per sq. in.)	9—10	6—7
Melting point	1150° C.	1200° C.
Hardness	24	35
Heat conductivity	10	8
Electrical resistance	8	16
Contraction per ft. in casting ..	3/32	9/32
Crushing strength, 1 in. cubes	40 tons	34 tons

In actual practice I have been able to maintain nearly all these figures, although the results vary somewhat according to the variation of the alloys.

Since the outbreak of war, acid-resisting iron has played no small part in the construction of plant for the production of propellants and high explosives. For the condensation of nitric acid, this metal was found a great boon, as plant of large capacity had to be rapidly erected at short notice, and it was found practicable to instal many large nitric acid plants of acid-resisting iron very rapidly—a result which could not have been effected by using pottery owing to the excessive length of time required for its manufacture. In addition, it was found that acid-resisting iron possessed a much higher efficiency owing to its heat conductivity being greater than that of earthenware. The heat-transmitting power of acid-resisting iron has been calculated to be nearly 10 times the heat-conductivity of stoneware or quartz, consequently parts of plant intended for conducting heat may be made of considerably smaller dimensions than would be the case if such parts were made of stoneware. The heat-transmitting power is about twice that of lead. A condenser built of acid-resisting iron condensed a charge of nitric acid in 16 hours, which was usually found to take 36 hours with a similar condenser built in pottery.

A further wide application of acid-resisting iron has been its use in connection with plant for concentration of sulphuric acid—a very large number of installations having been built up of cascade type as well as modifications of Kessler and other types of plant for rectification of sulphuric acid and re-concentration of waste acids from explosives manufacture. Its use is becoming daily of wider application, and whilst primarily it has been adopted as a metal to resist sulphuric and nitric acids, it is becoming more and more useful for other acids such as hydrochloric, acetic, citric, etc.

In spite of the success already attained, there are still factors of difficulty to be overcome. All alloys of low silicon content, say under 10%, are attacked very readily by sulphuric, hydrochloric, acetic, and citric acids. These alloys are not exceedingly brittle, but alloys containing from 16% to 18% silicon, whilst they are exceedingly resistant to sulphuric, hydrochloric, nitric, acetic, and citric acids, are extremely brittle, and are so very hard that it is impossible to machine them in any other way than by grinding with high-speed abrasive wheels. These points are decided drawbacks in many cases against the utilisation of acid-resisting iron, and experiments are still being continued to improve the tensile strength of the metal and produce an alloy that will be both malleable and machinable.

Notwithstanding the specific drawbacks already mentioned, it is possible to provide parts with

flanges and faces carefully ground on the surface to a very high and accurate finish, so that pipes of large and small diameters may be carefully jointed together without leakage.

Certain definite points must be held in mind in designing parts of plant or apparatus for manufacture in these acid-resisting irons. All joints in pipe work and vessels should be formed by means of flanges or spigot and socket, since the metal is too hard to screw or to take a screwed thread, and it is preferable so to design pipes and cored castings, that the use of chaplets can be avoided as far as possible. Another point in design is that all sharp corners must as far as possible be avoided, owing to the considerable shrinkage in cooling which has already been mentioned, otherwise sharp corners will become a source of weakness, and the vessel is very likely to sustain a fracture through strains set up by shrinkage in cooling. For the same reason all vessels such as boiling pans, receivers, stills, should be made curved at the bottom, as large flat surfaces present difficulties through contraction of the castings.

Few of these acid-resisting irons can be recommended for vessels which are required to be worked at high internal pressures, and it is not usually considered safe to use pressure vessels for any internal pressure higher than 50 lb. per square inch, excepting in cases where the vessels are of quite small diameter.

As already mentioned, the melting point of acid-resisting iron is considerably higher than that of ordinary cast iron, and this for many purposes is a decided advantage. In a statement made last year before the American Institute of Chemical Engineers, a case was mentioned regarding some nitric acid works equipped almost entirely with plant of acid-resisting iron. The works sustained a serious fire after being in operation for some 8 months, during which time no corrosion or breakages occurred with the plant, and whilst the fire destroyed the building, the acid-resisting plant was found to be unharmed, and 80% of the material was recovered and is still in use. It is questionable whether similar apparatus constructed of stoneware or other ceramic material could have withstood so unexpected a test.

Apart from the actual construction of chemical plant, these alloys have a wide application, such as in manufacturing anodes in connection with electro-metallurgical processes. After the outbreak of war, it was found impossible to obtain magnetite anodes, since these were chiefly made in Germany, and a substitute was found in acid-resisting iron. Whilst the material is not absolutely unacted upon when used as an anode in copper sulphate solution, many times its original weight of copper can be deposited before the anode shows serious signs of corrosion. The mechanical strength of the acid-resisting iron is a further decided advantage, although a little higher electrical energy is required than with anodes made of magnetite. Some experiments made in 1915 at the University of Illinois* disclosed remarkable properties, which proved the metal to be superior to many other metals for certain electro-magnetic machinery, and, with the addition of aluminium, the magnetic properties of the metal were greatly improved and increased toughness resulted.

DISCUSSION.

Capt. GOODWIN said that some 10 or 15 different makes of acid-resisting irons showed curious differences in composition. The average silicon content was about 15% in the United States and yet one sample would contain about 0.3% manganese and another 21%. He was able to confirm what Mr. Tungay had said as to hydrochloric acid,

particularly hot acid, and also to some extent as to chlorine. As far as he knew there was only one acid-resisting iron which would withstand their action satisfactorily and that had a high silicon content, viz., 16 to 20%, together with a small percentage of rare metal, the name of which he was not at liberty to mention. The skin of silicon iron castings was different from the body, and while usually the action on the skin was not greater than on the body, yet some materials such as hot ammonium chloride attacked the skin more rapidly. Further research was also necessary regarding the action of acetic acid. He believed that most castings of acid-resisting iron were pickled before they were sent out to see if acid would attack them or not. That suggested the necessity for investigation from the electrochemical point of view. In the design of plant he thought there had been too great a tendency to copy designs of apparatus usually adopted when stoneware or silica was used. Flanges in the pipes were frequently used, but were a source of weakness owing to the unequal contraction on cooling, and he suggested the use of conical buttress joints. Apparatus had also been put on the market for which acid-resisting iron was economically unsuitable, e.g., nitric acid retorts and fans, which latter, owing to considerations of strength and speed, would not give more than one inch draught. The future belonged to all kinds of acid-resisting metals, lacquers, and varnishes, and not only to iron. An acid-resisting aluminium would be extremely useful and was already on the American market.

Mr. SWINDIN said that he regarded these irons as glasses rather than as metals in the ordinary sense of the term, owing to their extreme brittleness. If in using acid-resisting iron manufacturers never made anything very large, kept it always in the form of a pipe, never made anything very flat, and kept away from flanges wherever possible, they would have very little trouble. The hardness was a nuisance. The use of these irons was bound to increase because of the rise of a new industry—the concentration of weak nitric acid produced from the fixation of atmospheric nitrogen. The physical constants of these alloys as given by the author were too generous to be accepted. The tensile stress to which the metal could be subjected meant nothing. Some lucky test piece might be satisfactory in this respect, but no one would rely upon the test. The next advance in the manufacture of these alloys must be in the direction of toughness.

Mr. GARDNER said that the figures given for corrosion were of little value since the area exposed was not given.

Mr. W. L. OAKDEN asked if acid-resisting iron had been tried in the construction of ordinary sulphuric acid chambers in place of lead, and how it compared as regards cost. Had this material been used in the Glover tower for the ordinary sulphuric acid process? The inlet pipe of this tower was soon subject to corrosion.

Mr. J. W. HINCHLEY suggested to the author that when he compared ordinary cast iron with acid-resisting iron he should choose a good chemical iron. The one selected was an agricultural implement iron. The silicon and the graphite were far too high and the combined carbon was too low, whilst the proportions of phosphorus, manganese, and sulphur were bad. Referring to the author's table, he particularly drew attention to the shrinkage of 3/32 in. in the case of cast iron, and 9/32 in. in the case of acid-resisting iron. The shrinkage in the case of cast iron was not all contraction: it was the difference between contraction on cooling and expansion due to the separation of graphite. If the cast iron had no graphite the shrinkage would be the same as that of the acid-resisting iron. The best acid-resisting irons were those free from graphite,

* Univ. Illinois Exp. Stat., Bull. 95.

and manufacturers should really make it their business to produce such a material. To do this it was necessary to melt the materials in the electric furnace, and the kind of furnace must be chosen with a view to keeping carbon away from the material. The question of machining was not so hopeless as some might think. It was possible to drill and machine some brands fairly satisfactorily if it were done carefully and the tools properly chosen.

Mr. H. M. RIDGE asked if the author had observed any action due to the presence of carbides; were these separated out in the high-silicon metal and, if so, were they appreciably attacked by acids when the vessels were in use? The author had not referred to the use of acid-resisting iron or steel for cutlery; it was well known that chromium was used for that purpose.

Mr. C. H. ALLDREE pointed out that the results given in the paper were chiefly with rather strong acids. He had found that whereas with sulphuric acid above 20%, or even above 10%, the metal would stand very well, when the percentage was lower, say from 2 to $\frac{1}{2}$ %, there was difficulty. In the case of a pump for pumping weak acid, the parts were destroyed almost as quickly as ordinary cast iron and particularly the piston, which had been ground and freed from skin. Further, one portion would be acted upon more rapidly than another. He had not found any material that would withstand hydrochloric acid.

Mr. C. O. BANNISTER said that although it was simple to make materials that would withstand the action of strong acids, one primary cause of failure was porosity of the casting. Sometimes this porosity was quite minute and was only discernible under the microscope. Another difficulty was graphite, and in spite of what Mr. Hinchley had said he was afraid this would never be got rid of. The best thing to do was to get it in a finely divided state and evenly distributed throughout the casting. The sulphur and phosphorus should be kept to the lowest possible limit. As to the divergence in the amount of manganese, he had found castings varying from 0.5 to 2% manganese behave perfectly well.

Mr. WALTER REID said that one method of removing the stresses which sometimes gave rise to fracture when a strain came upon flanges and similar parts of castings, was to treat the portion in which the strain existed to the heat of an oxy-acetylene blowpipe; after cooling the metal was very much stronger. It was also possible that heat treatment such as had been found so useful with steel, applied after casting, would result in the metal being very much tougher and more resistant to shock than it was at present.

Mr. TUNGAY replied that the actions of hydrochloric acid and chlorine were being investigated. The output of this iron had recently been largely confined to nitric and sulphuric acid plants, and the question of hydrochloric acid had not been of paramount importance. The skin of the casting was more easily attacked than the body, as had been suggested. The skin consisted generally of free particles of iron which adhered in the cooling, and on cooling it seemed to detach itself partially in the form of a scale and was rapidly attacked and cleaned off in pickling. He could not agree with Mr. Swindin that this iron was of the nature of a glass, as it would stand very much heavier treatment and altogether had much greater capabilities. In reply to Mr. Hinchley, he said that the cast iron taken for comparison was normal quality cast iron, taken out of Ryland's list.

Mr. HINCHLEY pointed out that that was pig iron.

Mr. TUNGAY agreed that the analysis was that of ordinary pig iron. In reply to Mr. Ridge, he said that carbides had separated out of the metal on cooling

and it was the separation of the carbides that at times caused great trouble. He had used low strength acids on some acid-resisting iron and had found quite satisfactory results. Porosity was one of the greatest difficulties and the endeavour was to keep the graphite as low as possible.

Nottingham Section.

Meeting held at University College, Nottingham, on Wednesday, February 20th, 1918.

DR. R. M. CAVEN IN THE CHAIR.

THE ANALYSIS OF ALUMINIUM ALLOYS.

BY BERNARD COLLITT AND WILLIAM REGAN, B.S.C.

The use of alloys of aluminium in the construction of aircraft and other engines of warfare necessitates very numerous analyses of the alloys, and requires, moreover, that the results of such analyses be available in the shortest possible time after the receipt of the samples.

During the past two or three years, we have been called upon to examine a considerable number of these light alloys, and have naturally been much interested in two important papers on the subject which have recently appeared by W. H. Withey* and J. H. Stansbie† respectively.

Our work was carried out several months before the publication of Mr. Stansbie's paper, and we find ourselves in agreement with him on the following points:—

1. That for rapid working it is advisable to "open out" the alloys with a solution of caustic soda for the determination of most of the alloying metals.

2. That on filtering the resulting alkaline solution, practically all the aluminium and zinc are to be found in the filtrate, whilst copper, iron, nickel, magnesium, and all the manganese except a trace, are left as a residue on the filter paper.

3. That a small amount of aluminium accompanies the copper, iron, etc., so that the iron cannot be estimated gravimetrically by precipitation with ammonia.

The alloys which we have examined may be divided into three classes or groups, as follows:—

Class I.—Alloys containing between 10 and 15% of copper, with or without about 1% of manganese.

Class II.—Alloys containing 10 to 20% of zinc, up to 5% of copper, and small amounts of any of the following metals: iron, nickel, manganese, and magnesium.

Class III.—Alloys containing up to 5% of copper and one or more of the following metals in amounts not usually exceeding $1\frac{1}{2}$ or 2%: iron, nickel, manganese, zinc, magnesium.

Lead and tin were not present in appreciable amounts in the alloys which came under our notice.

In Class I. alloys, we prefer to estimate copper by a volumetric method, and in Classes II. and III. to determine it gravimetrically. We have avoided the separation and estimation of copper by electrolysis, as we consider that the methods outlined below are quite as accurate, and are more rapid, especially when dealing with large numbers of samples.

Alloys of Class I.

In order to comply with certain specifications, these alloys must contain copper and manganese

* This J., 1916, 472.

† This J., 1917, 802.

within stated limits, and the chemical analysis is therefore usually confined to the determination of these two metals.

Copper.—One gram of fine drillings of the alloy is weighed out into a 400 c.c. tall beaker and 30 c.c. of solution of sodium hydroxide (15%) is added, or the alloy is covered with 100 c.c. of distilled water, and about 5 grms. of sodium peroxide added in small portions. The beaker is kept covered by a clock glass until violent reaction has ceased. The sides of the beaker are then washed down with a little water and the solution boiled until the alloy is thoroughly decomposed. After dilution with hot water to about 250 c.c. the solution is again boiled for a short time and then the precipitate of metallic copper and manganese quickly settles out and can be filtered off and washed with hot water. The filtrate is rejected; the residue is dissolved on the filter into a 300 c.c. conical flask by means of hot nitric acid (sp.gr. 1.18) and the filter paper washed free from copper and manganese with hot water and hot dilute nitric acid. The solution of copper is now evaporated to very small bulk, diluted slightly, 5 c.c. of ammonia solution (sp.gr. 0.90) is added, and the contents of the flask boiled for at least one minute. After cooling, 6 c.c. of glacial acetic acid is added, then 50 c.c. of sodium fluoride solution, followed by 10 to 15 c.c. of solution of potassium iodide (25 grms. in 100 c.c.). The solution is now ready for titration with standard solution of sodium thiosulphate, starch indicator being added when the colour of the solution shows that very little free iodine remains.

The standard solution of sodium thiosulphate is prepared by dissolving 400 grms. of the pure salt in distilled water and diluting to ten litres; 1 c.c. equals approximately 0.01 gm. Cu. The solution is standardised against the purest electrolytic copper. Particular attention is directed to the use of sodium fluoride, as suggested by Fraser,* in order to eliminate the interfering effect of any iron present in the solution to be titrated. The sodium fluoride solution is made up by saturating distilled water with the salt, filtering, and diluting 500 c.c. of the filtrate with distilled water to one litre.

In connection with the analysis, or rather with the sampling of these alloys containing 10 to 15% of copper, it should be noted that they are subject to liquation when in the molten condition, and unless suitable precautions are taken, castings poured from the same crucible or melting pot may contain considerably different percentages of copper, as shown by the following figures:—

Melt S.		Melt H.B.3.	
Casting No.	% Cu.	Casting No.	% Cu.
1.	12.52	1.	12.29
2.	12.80	3.	12.54
3.	13.03	5.	12.79
4.	13.20		

Melt II.C.		Melt II.D.	
Casting No.	% Cu.	Casting No.	% Cu.
1.	11.71	1.	11.21
2.	11.61	2.	11.54

7.	12.94	7.	13.87
8.	13.04	8.	13.06

* This Journal, 1915, 162.

Manganese.—Two of the volumetric methods, suitably modified, used for the determination of this element in steel, were tried, and gave excellent results, both as regards accuracy and rapidity. The second method, which involves no separation or filtration, is particularly speedy.

(1) One gm. of the alloy is weighed out into a 300 c.c. conical flask and 25 c.c. of solution of sodium hydroxide (15%) is added. The mixture is heated until the alloy is completely decomposed, then cooled, nitric acid (sp.gr. 1.42) is added until the solution is just acid, and then 35 c.c. of the same acid in excess. The mixture is boiled until everything is in solution, diluted with 35 c.c. of water and a little sodium bismuthate added. After boiling, the permanganate colour (or the precipitated manganese dioxide) is destroyed with a few drops of sulphurous acid solution, and all nitrous fumes boiled off. The solution is then cooled, and when quite cold, and after adding 1 gm. of sodium bismuthate, is shaken well, allowed to stand for a few minutes, filtered through asbestos or through an alundum crucible into a large conical flask, washed with dilute nitric acid, and titrated with standard solution of sodium arsenite, approximately $N/10$. It is advisable to standardise the arsenite solution against standard permanganate in a solution of the same volume and containing approximately the same amount of copper as the alloy solution to be titrated.

It is probable that the preliminary oxidation with bismuthate and subsequent reduction might be omitted altogether without affecting the accuracy of the results.

(2) One gm. of the alloy is weighed out into a 250 c.c. graduated flask of resistance glass, 25 c.c. of a solution of sodium hydroxide added, and the alloy decomposed as in method (1). After cooling, 90 c.c. of nitric acid (sp.gr. 1.18) is added, and solution completed by boiling, which is continued until all nitrous fumes are expelled. The solution is well cooled, diluted to the mark with distilled water, and mixed thoroughly. Into a 300 c.c. conical flask 50 c.c. (0.2 gm. alloy) is pipetted off, 25 c.c. of silver nitrate solution (2 grms. per litre) added, and the contents heated to boiling. Five c.c. of solution of ammonium persulphate (15%) is added, the flask immersed in boiling water for one minute, cooled, 80 c.c. of cold distilled water added, and the solution titrated with standard solution of sodium arsenite. The sodium arsenite solution should be of such strength that 1 c.c. = 0.01% Mn when working upon 0.2 gm. of alloy.

In cases where it is certain that the alloy is quite homogeneous, the determination may be shortened by weighing 0.2 gm. of alloy direct into a 300 c.c. conical flask, instead of weighing out 1 gm. of the alloy, dissolving, and taking an aliquot part of the solution.

Alloys in classes II. and III.

Silicon is estimated in the usual way by evaporating the solution of the metal with sulphuric acid, and in the filtrate from silica the copper is precipitated as sulphide, filtered out, washed, ignited, and weighed as oxide.

Silicon.—Two grms. of alloy is weighed out into a 500 c.c. tall beaker, and a mixture of 30 c.c. of hydrochloric acid (sp.gr. 1.16) and 10 c.c. of nitric acid (sp.gr. 1.42) is added very carefully, as the reaction with the alloy is violent. When all the mixture of acids has been added and the violence of the reaction has subsided, 30 c.c. of sulphuric acid (sp.gr. 1.84) is added and the solution of the alloy evaporated until the sulphates of metals have separated out and copious fumes of sulphur trioxide are evolved. The beaker and contents are allowed to cool, and about 200 c.c. of hot water is added and the separated sulphates dissolved by boiling. The residue is collected on

an ashless filter paper, thoroughly washed with hot water, ignited, and weighed as silica or as a mixture of silica and graphitic silicon.

Copper.—The filtrate and washings, about 350 c.c. in volume, are collected in a 600 c.c. beaker, heated almost to boiling, and the copper precipitated by the addition of two or three grms. of sodium thiosulphate crystals. On boiling, the precipitate of copper sulphide rapidly coagulates and can be filtered out very quickly, washed with hot water, ignited, and weighed as copper oxide.

Copper sulphide precipitated in the manner indicated is filtered out and washed with the greatest ease, and on ignition in an open muffle furnace is quickly converted into oxide. The method is not, however, recommended for alloys containing 10% and more of copper, as the results are not so good, probably owing to the fact that the conversion of sulphide to oxide is not completed so rapidly or thoroughly when igniting a comparatively large amount of precipitate. The following figures show what agreement may be expected when determining copper in this way; the volumetric results were obtained by the method described below, and used occasionally for comparative purposes.

Sample No.	Copper, % Gravimetric, weighed as CuO.	Copper, % Volumetric iodine titration.
13300	2.37 2.36	2.44
	2.37 2.39	2.36

Copper (alternative method), iron, and magnesium.

—Two grms. of the alloy is weighed out into a 500 c.c. beaker, dissolved in 100 c.c. of solution of sodium hydroxide (15%), diluted to about 300 c.c. with hot water and boiled, the residue of copper, iron, magnesium, etc., filtered out, washed with hot water, and the filter paper and residue returned to the original beaker; 10 c.c. hydrochloric acid (sp.gr. 1.16) and 10 c.c. nitric acid (sp.gr. 1.42) are then added, the mixture heated to complete solution of the metals, boiled, diluted, and filtered, and the precipitate washed with hot water and hot dilute hydrochloric acid. The bulk of filtrate and washings is kept as small as possible at this stage to prevent loss of time on subsequent evaporation. Ten c.c. of sulphuric acid (sp.gr. 1.84) is added and the solution evaporated until fumes of sulphur trioxide are evolved in order to drive off the other acids. The beaker and contents are allowed to cool, about 200 c.c. of hot water added, and the copper precipitated with a rapid stream of hydrogen sulphide, filtered, and washed with hydrogen sulphide water. The filtrate is reserved for determination of iron and magnesium. The copper sulphide on the filter paper is dissolved with hot nitric acid (sp.gr. 1.18) and washed alternately with hot water and hot nitric acid (sp.gr. 1.18), collecting the solution and washings in a 300 c.c. conical flask. The solution of copper is boiled down to very small bulk and the copper determined by titration with standard solution of thiosulphate exactly as described for alloys of Class I.

Iron.—The filtrate from the copper sulphide precipitation is boiled to free it from hydrogen sulphide, and a few drops of strong nitric acid added to oxidise the iron present. Three grms. of ammonium chloride is added, and a slight excess of ammonia solution (sp.gr. 0.90). The solution is now boiled; it is important that any aluminium which escaped solution in the treatment with

sodium hydroxide, but was dissolved in the acid mixture along with copper, iron, etc., be completely precipitated at this stage. The iron and aluminium hydroxides are filtered off and well washed with hot water, the filtrate and washings being reserved for the determination of magnesium. The residue of hydroxides, with the filter paper, is returned to the beaker in which precipitation took place, and 20 c.c. of hydrochloric acid (sp.gr. 1.16) added; the contents of the beaker are heated, diluted, and filtered into a 300 c.c. conical flask, and the residue of filter paper well washed with hot water and hot dilute hydrochloric acid. The acid solution of iron is then carefully reduced with solution of stannous chloride, excess of this reagent destroyed by a solution of mercuric chloride, the solution cooled thoroughly, diluted to a volume of 600 c.c. and titrated with standard N/10 or N/20 permanganate solution in the presence of phosphoric acid and manganese sulphate.

As it is necessary to separate iron before proceeding to the determination of magnesium, we prefer this process for estimating iron; in the case, however, of alloys which contain no magnesium, or in which its determination is not required, the following more rapid method for iron gives results which are sufficiently accurate for most purposes.

The alloy is decomposed in caustic soda solution as previously described, the copper, iron, nickel, etc., filtered out, washed, and dissolved in hydrochloric and nitric acids, and the solution diluted and filtered. Enough solution of ammonia (sp.gr. 0.90) is now added to precipitate the iron and any aluminium present, and to form the dark blue solution of cuprammonium salt. This solution is boiled for a short time only, the iron and aluminium hydroxides filtered off, washed, dissolved, and the iron reduced and titrated as previously described.

Magnesium.—To the filtrate from the iron and aluminium hydroxides, which should be practically neutral, 2.5 c.c. of ammonia solution (sp. gr. 0.90) is added, the solution heated to about 70° C. and then saturated with hydrogen sulphide. The precipitated sulphides are filtered off and washed with water containing ammonium sulphide. The filtrate is acidified and reduced by evaporation; nitric acid is then added and the volume of solution further reduced by boiling down to small bulk. Any precipitated sulphur is filtered out and the residue washed with hot water. Twenty c.c. of solution of ammonium phosphate is next added, the solution neutralised with ammonia and then, with constant stirring, more of the ammonia solution (sp.gr. 0.90) is gradually added until it forms one-third of the volume of the contents of the beaker. The solution is stirred at intervals, allowed to stand 12 hours, filtered, the precipitate washed with dilute ammonia, the filter and precipitate dried, ignited gently at first and afterwards strongly, and weighed as $Mg_2P_2O_7$.

Manganese is determined exactly as described for alloys of Class I.

Nickel.—We consider that it is unnecessary to separate copper before precipitating the nickel with dimethylglyoxime.

Two grams of the alloy is decomposed as directed for determination of copper, iron, and magnesium, and the residual copper, iron, nickel, etc., filtered off, and washed. The filter and residue are returned to the original beaker, and the metals dissolved in 20 c.c. of hydrochloric acid (sp. gr. 1.16) and 5 c.c. of nitric acid (sp.gr. 1.42); the solution is boiled, diluted, and filtered, and the precipitate washed with hot water and hot dilute hydrochloric acid. Six grms. of tartaric acid is added, and the solution diluted to 400 c.c., and made slightly alkaline with ammonia solution (sp.gr. 0.90) and then faintly acid with hydrochloric acid. Thirty c.c. of alcoholic solution of

dimethylglyoxime (1%) is added, and then ammonia solution, drop by drop, with constant stirring, until the solution is faintly alkaline. The beaker is allowed to stand for one hour in a warm place, the solution filtered through a tared alundum or Gooch crucible, and the residue dried for 1½ hours at 103° C., cooled in a desiccator, and weighed. The nickel dimethylglyoxime contains 20.31% nickel.

Zinc.—For alloys of Class II., we have used the method described by Withey in the paper already referred to. For alloys of Class III. we decompose the alloy by means of solution of caustic soda, dilute, boil, filter, and in the filtrate precipitate the zinc as sulphide. This is filtered out, washed, dissolved in hydrochloric acid, and the zinc finally precipitated as zinc ammonium phosphate, which is ignited and weighed as zinc pyrophosphate.

Analyses of aluminium alloys.

	I.	II.	III. (a)	III. (b)	III. (c)	III. (d)

(by diff.)						

The alloys of Class III. are usually made by first preparing a rich alloy of copper, nickel, and aluminium, and adding this to the requisite weight of aluminium to produce an alloy of the desired composition. The magnesium is not included in the rich alloy (or hardener), but is added to the finished diluted alloy shortly before pouring. As it is necessary to analyse the rich alloy at times, the following methods of estimating the copper, nickel, and iron present are described.

Silicon and iron.—The latter element cannot conveniently be determined by treating the alloy with caustic soda solution, filtering out copper, nickel, iron, etc., and then precipitating the iron with ammonia, reducing with stannous chloride, and titrating, as the iron is accompanied by so much aluminium that the precipitate obtained on the addition of ammonia is far too large to filter and wash. The procedure followed is to dissolve 2 or 3 grms. of "hardener" in a mixture of hydrochloric and nitric acids in a 400 c.c. beaker; and when solution is complete, dilute with a little water, cool, and add 15 c.c. of sulphuric acid (sp.gr. 1.84). The solution is evaporated until fumes of sulphur trioxide are evolved, cooled, diluted, heated until all the sulphates are in solution, filtered, and the precipitate washed with hot water, dried, ignited, and weighed as SiO₂. The filtrate is heated to about 70° C., hydrogen sulphide is passed in until all the copper is precipitated, the liquid is filtered, the residue being rejected, and the hydrogen sulphide boiled off from the filtrate, when 5 c.c. of nitric acid (sp.gr. 1.42) and 50 c.c. of a solution of ammonium chloride (1 in 4) are added. The solution is boiled down to about 300 c.c. and a solution of sodium hydroxide (50%) added until all the precipitated aluminium hydroxide redissolves. The liquid is heated to boiling, the precipitate allowed to settle for a short time only, filtered, and washed once or twice with hot water. The filter and residue are replaced in the original beaker, digested with 25 c.c. of hydrochloric acid (sp.gr. 1.16) until all ferric hydroxide is in solution, diluted, filtered into a 300 c.c. conical flask, and the iron reduced with stannous chloride and titrated as usual with standard N/10 solution of permanganate.

Copper.—0.5 gm. of alloy is weighed into a 300 c.c. conical flask, dissolved in nitric acid (sp.gr. 1.18) and copper determined by the iodide method, titrating with standard solution of sodium thiosulphate.
